                db.SaveChanges();
            }
            return base.OnConnected();
        }

        public override Task OnDisconnected(bool stopCalled)
        {
            using (var db = new UserContext())
            {
                var connection = db.Connections.Find(Context.ConnectionId);
                connection.Connected = false;
                db.SaveChanges();
            }
            return base.OnDisconnected(stopCalled);
        }
    }
}
```

Azure table storage

The following Azure table storage example is similar to the database example. It does not include all of the information that you would need to get started with Azure Table Storage Service. For information, see How to use Table storage from .NET.

The following example shows a table entity for storing connection information. It partitions the data by user name, and identifies each entity by the connection id, so a user can have multiple connections at any time.

```
using Microsoft.WindowsAzure.Storage.Table;
using System;

namespace MapUsersSample
{
    public class ConnectionEntity : TableEntity
    {
        public ConnectionEntity() { }

        public ConnectionEntity(string userName, string connectionID)
        {
            this.PartitionKey = userName;
            this.RowKey = connectionID;
        }
    }
}
```

In the hub, you track the status of each user's connection.

```
using Microsoft.AspNet.SignalR;
using Microsoft.WindowsAzure;
using Microsoft.WindowsAzure.Storage;
using Microsoft.WindowsAzure.Storage.Table;
using System;
using System.Linq;
using System.Threading.Tasks;

namespace MapUsersSample
{
    public class ChatHub : Hub
    {
        public void SendChatMessage(string who, string message)
        {
            var name = Context.User.Identity.Name;

            var table = GetConnectionTable();

            var query = new TableQuery<ConnectionEntity>()
                .Where(TableQuery.GenerateFilterCondition(
                "PartitionKey",
                QueryComparisons.Equal,
                who));

            var queryResult = table.ExecuteQuery(query).ToList();
            if (queryResult.Count == 0)
            {
                Clients.Caller.showErrorMessage("The user is no longer connected.");
            }
            else
            {
                foreach (var entity in queryResult)
                {
                    Clients.Client(entity.RowKey).addChatMessage(name + ": " + message);
                }
            }
        }

        public override Task OnConnected()
        {
            var name = Context.User.Identity.Name;
            var table = GetConnectionTable();
            table.CreateIfNotExists();

            var entity = new ConnectionEntity(
                name.ToLower(),
                Context.ConnectionId);
```

```
            var insertOperation = TableOperation.InsertOrReplace(entity);
            table.Execute(insertOperation);

            return base.OnConnected();
        }

        public override Task OnDisconnected(bool stopCalled)
        {
            var name = Context.User.Identity.Name;
            var table = GetConnectionTable();

            var deleteOperation = TableOperation.Delete(
                new ConnectionEntity(name, Context.ConnectionId) { ETag = "*" });
            table.Execute(deleteOperation);

            return base.OnDisconnected(stopCalled);
        }

        private CloudTable GetConnectionTable()
        {
            var storageAccount =
                CloudStorageAccount.Parse(
                CloudConfigurationManager.GetSetting("StorageConnectionString"));
            var tableClient = storageAccount.CreateCloudTableClient();
            return tableClient.GetTableReference("connection");
        }
    }
}
```

SignalR Troubleshooting

2/20/2020 • 17 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document describes common troubleshooting issues with SignalR.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

This document contains the following sections.

- Calling methods between the client and server silently fails
- Configuring IIS websockets to ping/pong to detect a dead client
- Other connection issues
- Compilation and server-side errors
- Visual Studio issues
- Internet Information Services issues
- Microsoft Azure issues

Calling methods between the client and server silently fails

This section describes possible causes for a method call between client and server to fail without a meaningful error message. In a SignalR application, the server has no information about the methods that the client implements; when the server invokes a client method, the method name and parameter data are sent to the client, and the method is executed only if it exists in the format that the server specified. If no matching method is found on the client, nothing happens, and no error message is raised on the server.

To further investigate client methods not getting called, you can turn on logging before the calling the start method on the hub to see what calls are coming from the server. To enable logging in a JavaScript application, see How to enable client-side logging (JavaScript client version). To enable logging in a .NET client application, see How to enable client-side logging (.NET Client version).

Misspelled method, incorrect method signature, or incorrect hub name

If the name or signature of a called method does not exactly match an appropriate method on the client, the call will fail. Verify that the method name called by the server matches the name of the method on the client. Also, SignalR creates the hub proxy using camel-cased methods, as is appropriate in JavaScript, so a method called `SendMessage` on the server would be called `sendMessage` in the client proxy. If you use the `HubName` attribute in your server-side code, verify that the name used matches the name used to create the hub on the client. If you do not use the `HubName` attribute, verify that the name of the hub in a JavaScript client is camel-cased, such as chatHub instead of ChatHub.

Duplicate method name on client

Verify that you do not have a duplicate method on the client that differs only by case. If your client application has a method called `sendMessage`, verify that there isn't also a method called `SendMessage` as well.

Missing JSON parser on the client

SignalR requires a JSON parser to be present to serialize calls between the server and the client. If your client doesn't have a built-in JSON parser (such as Internet Explorer 7), you'll need to include one in your application. You can download the JSON parser here.

Mixing Hub and PersistentConnection syntax

SignalR uses two communication models: Hubs and PersistentConnections. The syntax for calling these two communication models is different in the client code. If you have added a hub in your server code, verify that all of your client code uses the proper hub syntax.

JavaScript client code that creates a PersistentConnection in a JavaScript client

```
var myConnection = $.connection('/echo');
```

JavaScript client code that creates a Hub Proxy in a Javascript client

```
var myHub = $.connection.MyHub;
```

C# server code that maps a route to a PersistentConnection

```
RouteTable.Routes.MapConnection<MyConnection>("my", "/echo");
```

C# server code that maps a route to a Hub, or to multiple hubs if you have multiple applications

```
App.MapSignalR();
```

Connection started before subscriptions are added

If the Hub's connection is started before methods that can be called from the server are added to the proxy, messages will not be received. The following JavaScript code will not start the hub properly:

Incorrect JavaScript client code that will not allow Hubs messages to be received

```
var chat = $.connection.chatHub;
$.connection.hub.start().done(function () {
    chat.client.broadcastMessage = function (name, message) {...};
});
```

Instead, add the method subscriptions before calling Start:

JavaScript client code that correctly adds subscriptions to a hub

```
var chat = $.connection.chatHub;
chat.client.broadcastMessage = function (name, message) {...};
    $.connection.hub.start().done(function () {
        ...
    });
```

Missing method name on the hub proxy

Verify that the method defined on the server is subscribed to on the client. Even though the server defines the method, it must still be added to the client proxy. Methods can be added to the client proxy in the following ways (Note that the method is added to the `client` member of the hub, not the hub directly):

JavaScript client code that adds methods to a hub proxy

```
// Method added to proxy in JavaScript:
myHubProxy.server.method1 = function (param1, param2) {...};
//Multiple methods added to proxy in JavaScript using jQuery:
$.extend(myHubProxy.server, {
    method1: function (param1, param2) {...},
    method2: function (param3, param4) {...}
});
```

Hub or hub methods not declared as Public

To be visible on the client, the hub implementation and methods must be declared as `public`.

Accessing hub from a different application

SignalR Hubs can only be accessed through applications that implement SignalR clients. SignalR cannot interoperate with other communication libraries (like SOAP or WCF web services.) If there is no SignalR client available for your target platform, you cannot access the server's endpoint directly.

Manually serializing data

SignalR will automatically use JSON to serialize your method parameters- there's no need to do it yourself.

Remote Hub method not executed on client in OnDisconnected function

This behavior is by design. When `OnDisconnected` is called, the hub has already entered the `Disconnected` state, which does not allow further hub methods to be called.

C# server code that correctly executes code in the OnDisconnected event

```
public class MyHub : Hub
{
    public override Task OnDisconnected()
    {
        // Do what you want here
        return base.OnDisconnected();
    }
}
```

OnDisconnect not firing at consistent times

This behavior is by design. When a user attempts to navigate away from a page with an active SignalR connection, the SignalR client will then make a best-effort attempt to notify the server that the client connection will be stopped. If the SignalR client's best-effort attempt fails to reach the server, the server will dispose of the connection after a configurable `DisconnectTimeout` later, at which time the `OnDisconnected` event will fire. If the SignalR client's best-effort attempt is successful, the `OnDisconnected` event will fire immediately.

For information on setting the `DisconnectTimeout` setting, see Handling connection lifetime events: DisconnectTimeout.

Connection limit reached

When using the full version of IIS on a client operating system like Windows 7, a 10-connection limit is imposed. When using a client OS, use IIS Express instead to avoid this limit.

Cross-domain connection not set up properly

If a cross-domain connection (a connection for which the SignalR URL is not in the same domain as the hosting page) is not set up correctly, the connection may fail without an error message. For information on how to enable cross-domain communication, see How to establish a cross-domain connection.

Connection using NTLM (Active Directory) not working in .NET client

A connection in a .NET client application that uses Domain security may fail if the connection is not configured properly. To use SignalR in a domain environment, set the requisite connection property as follows:

C# client code that implements connection credentials

```
connection.Credentials = CredentialCache.DefaultCredentials;
```

Configuring IIS websockets to ping/pong to detect a dead client

SignalR servers don't know if the client is dead or not and they rely on notification from the underlying websocket for connection failures, that is, the `OnClose` callback. One solution to this problem is to configure IIS websockets to do the ping/pong for you. This ensures that your connection will close if it breaks unexpectedly. For more information see this stackoverflow post.

Other connection issues

This section describes the causes and solutions for specific symptoms or error messages that occur during a connection.

"Start must be called before data can be sent" error

This error is commonly seen if code references SignalR objects before the connection is started. The wireup for handlers and the like that will call methods defined on the server must be added after the connection completes. Note that the call to `Start` is asynchronous, so code after the call may be executed before it completes. The best way to add handlers after a connection starts completely is to put them into a callback function that is passed as a parameter to the start method:

JavaScript client code that correctly adds event handlers that reference SignalR objects

```
$.connection.hub.start().done(function () {
    // Wire up Send button to call NewContosoChatMessage on the server.
    $('#newContosoChatMessage').click(function () {
        contosoChatHubProxy.server.newContosoChatMessage(
            $('#displayname').val(), $('#message').val());
            $('#message').val('').focus();
    });
```

This error will also be seen if a connection stops while SignalR objects are still being referenced.

"301 Moved Permanently" or "302 Moved Temporarily" error

This error may be seen if the project contains a folder called SignalR, which will interfere with the automatically-created proxy. To avoid this error, do not use a folder called `SignalR` in your application, or turn automatic proxy

generation off. See The Generated Proxy and what it does for you for more details.

"403 Forbidden" error in .NET or Silverlight client

This error may occur in cross-domain environments where cross-domain communication is not properly enabled. For information on how to enable cross-domain communication, see How to establish a cross-domain connection. To establish a cross-domain connection in a Silverlight client, see Cross-domain connections from Silverlight clients.

"404 Not Found" error

There are several causes for this issue. Verify all of the following:

- **Hub proxy address reference not formatted correctly:** This error is commonly seen if the reference to the generated hub proxy address is not formatted correctly. Verify that the reference to the hub address is made properly. See How to reference the dynamically generated proxy for details.
- **Adding routes to application before adding the hub route:** If your application uses other routes, verify that the first route added is the call to `MapSignalR`.
- **Using IIS 7 or 7.5 without the update for extensionless URLs:** Using IIS 7 or 7.5 requires an update for extensionless URLs so that the server can provide access to the hub definitions at `/signalr/hubs`. The update can be found here.
- **IIS cache out of date or corrupt:** To verify that the cache contents are not out of date, enter the following command in a PowerShell window to clear the cache:

```
net stop w3svc
Remove-Item -Path "C:\Windows\Microsoft.NET\Framework64\v4.0.30319\Temporary ASP.NET Files\root\*" -
Force -Recurse
net start w3svc
```

"500 Internal Server Error"

This is a very generic error that could have a wide variety of causes. The details of the error should appear in the server's event log, or can be found through debugging the server. More detailed error information may be obtained by turning on detailed errors on the server. For more information, see How to handle errors in the Hub class.

This error is also commonly seen if a firewall or proxy is not configured properly, causing the request headers to be rewritten. The solution is to make sure that port 80 is enabled on the firewall or proxy.

"Unexpected response code: 500"

This error may occur if the version of .NET framework used in the application does not match the version specified in Web.Config. The solution is to verify that .NET 4.5 is used in both the application settings and the Web.Config file.

"TypeError: <hubType> is undefined" error

This error will result if the call to `MapSignalR` is not made properly. See How to register SignalR Middleware and configure SignalR options for more information.

JsonSerializationException was unhandled by user code

Verify that the parameters you send to your methods do not include non-serializable types (like file handles or database connections). If you need to use members on a server-side object that you don't want to be sent to the client (either for security or for reasons of serialization), use the `JSONIgnore` attribute.

"Protocol error: Unknown transport" error

This error may occur if the client does not support the transports that SignalR uses. See Transports and Fallbacks

for information on which browsers can be used with SignalR.

"JavaScript Hub proxy generation has been disabled."

This error will occur if `DisableJavaScriptProxies` is set while also including a reference to the dynamically generated proxy at `signalr/hubs`. For more information on creating the proxy manually, see The generated proxy and what it does for you.

"The connection ID is in the incorrect format" or "The user identity cannot change during an active SignalR connection" error

This error may be seen if authentication is being used, and the client is logged out before the connection is stopped. The solution is to stop the SignalR connection before logging the client out.

"Uncaught Error: SignalR: jQuery not found. Please ensure jQuery is referenced before the SignalR.js file" error

The SignalR JavaScript client requires jQuery to run. Verify that your reference to jQuery is correct, that the path used is valid, and that the reference to jQuery is before the reference to SignalR.

"Uncaught TypeError: Cannot read property '<property>' of undefined" error

This error results from not having jQuery or the hubs proxy referenced properly. Verify that your reference to jQuery and the hubs proxy is correct, that the path used is valid, and that the reference to jQuery is before the reference to the hubs proxy. The default reference to the hubs proxy should look like the following:

HTML client-side code that correctly references the Hubs proxy

```
<script src="/signalr/hubs"></script>
```

"RuntimeBinderException was unhandled by user code" error

This error may occur when the incorrect overload of `Hub.On` is used. If the method has a return value, the return type must be specified as a generic type parameter:

Method defined on the client (without generated proxy)

```
MyHub.On<ReturnType>("MethodName", LocalMethod);
```

Connection ID is inconsistent or connection breaks between page loads

This behavior is by design. Since the hub object is hosted in the page object, the hub is destroyed when the page refreshes. A multi-page application needs to maintain the association between users and connection IDs so that they will be consistent between page loads. The connection IDs can be stored on the server in either a `ConcurrentDictionary` object or a database.

"Value cannot be null" error

Server-side methods with optional parameters are not currently supported; if the optional parameter is omitted, the method will fail. For more information, see Optional Parameters.

"Firefox can't establish a connection to the server at <address>" error in Firebug

This error message can be seen in Firebug if negotiation of the WebSocket transport fails and another transport is used instead. This behavior is by design.

"The remote certificate is invalid according to the validation procedure" error in .NET client application

If your server requires custom client certificates, then you can add an x509certificate to the connection before the request is made. Add the certificate to the connection using `Connection.AddClientCertificate`.

Connection drops after authentication times out

This behavior is by design. Authentication credentials cannot be modified while a connection is active; to refresh

credentials, the connection must be stopped and restarted.

OnConnected gets called twice when using jQuery Mobile

jQuery Mobile's `initializePage` function forces the scripts in each page to be re-executed, thus creating a second connection. Solutions for this issue include:

- Include the reference to jQuery Mobile before your JavaScript file.
- Disable the `initializePage` function by setting `$.mobile.autoInitializePage = false`.
- Wait for the page to finish initializing before starting the connection.

Messages are delayed in Silverlight applications using Server Sent Events

Messages are delayed when using server sent events on Silverlight. To force long polling to be used instead, use the following when starting the connection:

```
connection.Start(new LongPollingTransport());
```

"Permission Denied" using Forever Frame protocol

This is a known issue, described here. This symptom may be seen using the latest JQuery library; the workaround is to downgrade your application to JQuery 1.8.2.

"InvalidOperationException: Not a valid web socket request.

This error may occur if the WebSocket protocol is used, but the network proxy is modifying the request headers. The solution is to configure the proxy to allow WebSocket on port 80.

"Exception: <method name> method could not be resolved" when client calls method on server

This error can result from using data types that cannot be discovered in a JSON payload, such as Array. The workaround is to use a data type that is discoverable by JSON, such as IList. For more information, see .NET Client unable to call hub methods with array parameters.

Compilation and server-side errors

The following section contains possible solutions to compiler and server-side runtime errors.

Reference to Hub instance is null

Since a hub instance is created for each connection, you can't create an instance of a hub in your code yourself. To call methods on a hub from outside the hub itself, see How to call client methods and manage groups from outside the Hub class for how to obtain a reference to the hub context.

HTTPContext.Current.Session is null

This behavior is by design. SignalR does not support the ASP.NET session state, since enabling the session state would break duplex messaging.

No suitable method to override

You may see this error if you are using code from older documentation or blogs. Verify that you are not referencing names of methods that have been changed or deprecated (like `OnConnectedAsync`).

HostContextExtensions.WebSocketServerUrl is null

This behavior is by design. This member is deprecated and should not be used.

"A route named 'signalr.hubs' is already in the route collection" error

This error will be seen if `MapSignalR` is called twice by your application. Some example applications call `MapSignalR` directly in the Startup class; others make the call in a wrapper class. Ensure that your application does not do both.

WebSocket is not used

If you have verified that your server and clients meet the requirements for WebSocket (listed in the Supported Platforms document), you will need to enable WebSocket on your server. Instructions for doing this can be found here.

$.connection is undefined

This error indicates that either the scripts on a page are not being loaded properly, or the hub proxy is not reachable or is being accessed incorrectly. Verify that the script references on your page correspond to the scripts loaded in your project, and that /signalr/hubs can be accessed in a browser when the server is running.

One or more types required to compile a dynamic expression cannot be found

This error indicates that the `Microsoft.CSharp` library is missing. Add it in the **Assemblies->Framework** tab.

Caller state cannot be accessed from Clients.Caller in Visual Basic or in a strongly typed hub; "Conversion from type 'Task(Of Object)' to type 'String' is not valid" error

To access caller state in Visual Basic or in a strongly typed hub, use the `Clients.CallerState` property (introduced in SignalR 2.1) instead of `Clients.Caller`.

Visual Studio issues

This section describes issues encountered in Visual Studio.

Script Documents node does not appear in Solution Explorer

Some of our tutorials direct you to the "Script Documents" node in Solution Explorer while debugging. This node is produced by the JavaScript debugger, and will only appear while debugging browser clients in Internet Explorer; the node will not appear if Chrome or Firefox are used. The JavaScript debugger will also not run if another client debugger is running, such as the Silverlight debugger.

SignalR does not work on Visual Studio 2008 or earlier

This behavior is by design. SignalR requires .NET Framework 4 or later; this requires that SignalR applications be developed in Visual Studio 2010 or later. The server component of SignalR requires .NET Framework 4.5.

IIS issues

This section contains issues with Internet Information Services.

SignalR works on Visual Studio development server, but not in IIS

SignalR is supported on IIS 7.0 and 7.5, but support for extensionless URLs must be added. To add support for extensionless URLs, see https://support.microsoft.com/kb/980368

SignalR requires ASP.NET to be installed on the server (ASP.NET is not installed on IIS by default). To install ASP.NET, see ASP.NET Downloads.

Microsoft Azure issues

This section contains issues with Microsoft Azure.

FileLoadException when hosting SignalR in an Azure Worker Role

Hosting SignalR in an Azure Worker Role might result in the exception "Could not load file or assembly 'Microsoft.Owin, Version=2.0.0.0". This is a known issue with NuGet; Binding redirects are not added automatically in Azure Worker Role projects. To fix this, you can add the binding redirects manually. Add the following lines to the `app.config` file for your Worker Role project.

```
<runtime>
  <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
    <dependentAssembly>
      <assemblyIdentity name="Microsoft.Owin" publicKeyToken="31bf3856ad364e35" culture="neutral" />
      <bindingRedirect oldVersion="0.0.0.0-2.0.2.0" newVersion="2.0.2.0" />
    </dependentAssembly>
    <dependentAssembly>
      <assemblyIdentity name="Microsoft.Owin.Security" publicKeyToken="31bf3856ad364e35" culture="neutral" />
      <bindingRedirect oldVersion="0.0.0.0-2.0.2.0" newVersion="2.0.2.0" />
    </dependentAssembly>
  </assemblyBinding>
</runtime>
```

Messages are not received through the Azure backplane after altering topic names

The topics used by the Azure backplane are maintained internally; they are not intended to be user-configurable.

Unit Testing SignalR Applications

2/20/2020 • 4 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This article describes using the Unit Testing features of SignalR 2.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Unit testing SignalR applications

You can use the unit test features in SignalR 2 to create unit tests for your SignalR application. SignalR 2 includes the IHubCallerConnectionContext interface, which can be used to create a mock object to simulate your hub methods for testing.

In this section, you'll add unit tests for the application created in the Getting Started tutorial using XUnit.net and Moq.

XUnit.net will be used to control the test; Moq will be used to create a mock object for testing. Other mocking frameworks can be used if desired; NSubstitute is also a good choice. This tutorial demonstrates how to set up the mock object in two ways: First, using a `dynamic` object (introduced in .NET Framework 4), and second, using an interface.

Contents

This tutorial contains the following sections.

- Unit testing with Dynamic
- Unit testing by type

Unit testing with Dynamic

In this section, you'll add a unit test for the application created in the Getting Started tutorial using a dynamic object.

1. Install the XUnit Runner extension for Visual Studio 2013.
2. Either complete the Getting Started tutorial, or download the completed application from MSDN Code Gallery.

3. If you are using the download version of the Getting Started application, open **Package Manager Console** and click **Restore** to add the SignalR package to the project.

4. Add a project to the solution for the unit test. Right-click your solution in **Solution Explorer** and select **Add**, **New Project...**. Under the **C#** node, select the **Windows** node. Select **Class Library**. Name the new project **TestLibrary** and click **OK**.

5. Add a reference in the test library project to the SignalRChat project. Right-click the **TestLibrary** project and select **Add**, **Reference...**. Select the **Projects** node under the **Solution** node, and check **SignalRChat**. Click **OK**.

6. Add the SignalR, Moq, and XUnit packages to the **TestLibrary** project. In the **Package Manager Console**, set the **Default Project** dropdown to **TestLibrary**. Run the following commands in the console window:

   - `Install-Package Microsoft.AspNet.SignalR`

- `Install-Package Moq`
- `Install-Package XUnit`

7. Create the test file. Right-click the **TestLibrary** project and click **Add...**, **Class**. Name the new class **Tests.cs**.

8. Replace the contents of Tests.cs with the following code.

```
using System;
using Xunit;
using SignalRChat;
using Microsoft.AspNet.SignalR.Hubs;
using Moq;
using System.Dynamic;

namespace TestLibrary
{
    public class Tests
    {
        [Fact]
        public void HubsAreMockableViaDynamic()
        {
            bool sendCalled = false;
            var hub = new ChatHub();
            var mockClients = new Mock<IHubCallerConnectionContext<dynamic>>();
            hub.Clients = mockClients.Object;
            dynamic all = new ExpandoObject();
            all.broadcastMessage = new Action<string, string>((name, message) => {
                sendCalled = true;
            });
            mockClients.Setup(m => m.All).Returns((ExpandoObject)all);
            hub.Send("TestUser", "TestMessage");
            Assert.True(sendCalled);
        }
    }
}
```

In the code above, a test client is created using the `Mock` object from the Moq library, of type IHubCallerConnectionContext (in SignalR 2.1, assign `dynamic` for the type parameter.) The `IHubCallerConnectionContext` interface is the proxy object with which you invoke methods on the client. The `broadcastMessage` function is then defined for the mock client so that it can be called by the `ChatHub` class. The test engine then calls the `Send` method of the `ChatHub` class, which in turn calls the mocked `broadcastMessage` function.

9. Build the solution by pressing **F6**.

10. Run the unit test. In Visual Studio, select **Test**, **Windows**, **Test Explorer**. In the Test Explorer window, right-click **HubsAreMockableViaDynamic** and select **Run Selected Tests**.

11. Verify that the test passed by checking the lower pane in the Test Explorer window. The window will show that the test passed.

Unit testing by type

In this section, you'll add a test for the application created in the Getting Started tutorial using an interface that contains the method to be tested.

1. Complete steps 1-7 in the Unit testing with Dynamic tutorial above.

2. Replace the contents of Tests.cs with the following code.

```
using Xunit;
using SignalRChat;
using Microsoft.AspNet.SignalR.Hubs;
using Moq;

namespace TestLibrary
{
    public class Tests
    {

       public interface IClientContract
       {
           void broadcastMessage(string name, string message);
       }
       [Fact]
       public void HubsAreMockableViaType()
       {
           var hub = new ChatHub();
           var mockClients = new Mock<IHubCallerConnectionContext<dynamic>>();
           var all = new Mock<IClientContract>();
           hub.Clients = mockClients.Object;
           all.Setup(m => m.broadcastMessage(It.IsAny<string>(),
                It.IsAny<string>())).Verifiable();
           mockClients.Setup(m => m.All).Returns(all.Object);
           hub.Send("TestUser", "TestMessage");
           all.VerifyAll();
       }
    }
}
```

In the code above, an interface is created defining the signature of the `broadcastMessage` method for which the test engine will create a mock client. A mock client is then created using the `Mock` object, of type IHubCallerConnectionContext (in SignalR 2.1, assign `dynamic` for the type parameter.) The `IHubCallerConnectionContext` interface is the proxy object with which you invoke methods on the client.

The test then creates an instance of `ChatHub`, and then creates a mock version of the `broadcastMessage` method, which in turn is invoked by calling the `Send` method on the hub.

3. Build the solution by pressing **F6**.

4. Run the unit test. In Visual Studio, select **Test**, **Windows**, **Test Explorer**. In the Test Explorer window, right-click **HubsAreMockableViaDynamic** and select **Run Selected Tests**.

5. Verify that the test passed by checking the lower pane in the Test Explorer window. The window will show that the test passed.

Enabling SignalR Tracing

2/20/2020 • 7 minutes to read • Edit Online

by Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document describes how to enable and configure tracing for SignalR servers and clients. Tracing enables you to view diagnostic information about events in your SignalR application.

This topic was originally written by Patrick Fletcher.

Software versions used in the tutorial

- Visual Studio 2013
- .NET Framework 4.5
- SignalR version 2

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

When tracing is enabled, a SignalR application creates log entries for events. You can log events from both the client and the server. Tracing on the server logs connection, scaleout provider, and message bus events. Tracing on the client logs connection events. In SignalR 2.1 and later, tracing on the client logs the full content of hub invocation messages.

Contents

- Enabling tracing on the server
  - Logging server events to text files
  - Logging server events to the event log
- Enabling tracing in the .NET client (Windows Desktop apps)
  - Logging Desktop client events to the console
  - Logging Desktop client events to a text file
- Enabling tracing in Windows Phone 8 clients
  - Logging Windows Phone client events to the UI
  - Logging Windows Phone client events to the debug console
- Enabling tracing in the JavaScript client

Enabling tracing on the server

You enable tracing on the server within the application's configuration file (either App.config or Web.config depending on the type of project.) You specify which categories of events you want to log. In the configuration file, you also specify whether to log the events to a text file, the Windows event log, or a custom log using an implementation of TraceListener.

The server event categories include the following sorts of messages:

SOURCE	MESSAGES
SignalR.SqlMessageBus	SQL Message Bus scaleout provider setup, database operation, error, and timeout events
SignalR.ServiceBusMessageBus	Service bus scaleout provider topic creation and subscription, error, and messaging events
SignalR.RedisMessageBus	Redis scaleout provider connection, disconnection, and error events
SignalR.ScaleoutMessageBus	Scaleout messaging events
SignalR.Transports.WebSocketTransport	WebSocket transport connection, disconnection, messaging, and error events
SignalR.Transports.ServerSentEventsTransport	ServerSentEvents transport connection, disconnection, messaging, and error events
SignalR.Transports.ForeverFrameTransport	ForeverFrame transport connection, disconnection, messaging, and error events
SignalR.Transports.LongPollingTransport	LongPolling transport connection, disconnection, messaging, and error events
SignalR.Transports.TransportHeartBeat	Transport connection, disconnection, and keepalive events
SignalR.ReflectedHubDescriptorProvider	Hub discovery events

Logging server events to text files

The following code shows how to enable tracing for each category of event. This sample configures the application to log events to text files.

XML server code for enabling tracing

```
<system.diagnostics>
    <sources>
      <source name="SignalR.SqlMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.ServiceBusMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.RedisMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
```

```
      </source>
      <source name="SignalR.ScaleoutMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.Transports.WebSocketTransport">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.ServerSentEventsTransport">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.ForeverFrameTransport">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.LongPollingTransport">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.TransportHeartBeat">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.ReflectedHubDescriptorProvider">
        <listeners>
          <add name="SignalR-Init" />
        </listeners>
      </source>
    </sources>
    <!-- Sets the trace verbosity level -->
    <switches>
      <add name="SignalRSwitch" value="Verbose" />
    </switches>
    <!-- Specifies the trace writer for output -->
    <sharedListeners>
      <!-- Listener for transport events -->
      <add name="SignalR-Transports" type="System.Diagnostics.TextWriterTraceListener"
initializeData="transports.log.txt" />
      <!-- Listener for scaleout provider events -->
      <add name="SignalR-Bus" type="System.Diagnostics.TextWriterTraceListener" initializeData="bus.log.txt"
/>
      <!-- Listener for hub discovery events -->
      <add name="SignalR-Init" type="System.Diagnostics.TextWriterTraceListener" initializeData="init.log.txt"
/>
    </sharedListeners>
    <trace autoflush="true" />
  </system.diagnostics>
```

In the code above, the `SignalRSwitch` entry specifies the TraceLevel used for events sent to the specified log. In this case, it is set to `Verbose` which means all debugging and tracing messages are logged.

The following output shows entries from the `transports.log.txt` file for an application using the above configuration file. It shows a new connection, a removed connection, and transport heartbeat events.

```
SignalR.Transports.TransportHeartBeat Information: 0 : Connection 9aa62c9b-09b3-416c-b367-06520e24f780 is New.
SignalR.Transports.TransportHeartBeat Verbose: 0 : KeepAlive(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.TransportHeartBeat Verbose: 0 : KeepAlive(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.TransportHeartBeat Verbose: 0 : KeepAlive(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.WebSocketTransport Information: 0 : CloseSocket(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.WebSocketTransport Information: 0 : Abort(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.TransportHeartBeat Information: 0 : Removing connection 9aa62c9b-09b3-416c-b367-
06520e24f780
SignalR.Transports.WebSocketTransport Information: 0 : End(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.WebSocketTransport Verbose: 0 : DrainWrites(9aa62c9b-09b3-416c-b367-06520e24f780)
SignalR.Transports.WebSocketTransport Information: 0 : CompleteRequest (9aa62c9b-09b3-416c-b367-06520e24f780)
```

Logging server events to the event log

To log events to the event log rather than a text file, change the values for the entries in the `sharedListeners` node. The following code shows how to log server events to the event log:

XML server code for logging events to the event log

```
<sharedListeners>
  <!-- Listener for transport events -->
  <add name="SignalR-Transports" type="System.Diagnostics.EventLogTraceListener"
initializeData="SignalRTransportLog" />
  <!-- Listener for scaleout provider events -->
  <add name="SignalR-Bus" type="System.Diagnostics.EventLogTraceListener" initializeData="SignalRScaleoutLog"
/>
  <!-- Listener for hub discovery events -->
  <add name="SignalR-Init" type="System.Diagnostics.EventLogTraceListener" initializeData="SignalRInitLog" />
</sharedListeners>
```

The events are logged in the Application log, and are available through the Event Viewer, as shown below:

> **NOTE**
>
> When using the event log, set the **TraceLevel** to **Error** to keep the number of messages manageable.

Enabling tracing in the .NET client (Windows Desktop apps)

The .NET client can log events to the console, a text file, or to a custom log using an implementation of TextWriter.

To enable logging in the .NET client, set the connection's `TraceLevel` property to a TraceLevels value, and the `TraceWriter` property to a valid TextWriter instance.

Logging Desktop client events to the console

The following C# code shows how to log events in the .NET client to the console:

```
var hubConnection = new HubConnection("http://www.contoso.com/");
hubConnection.TraceLevel = TraceLevels.All;
hubConnection.TraceWriter = Console.Out;
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await hubConnection.Start();
```

Logging Desktop client events to a text file

The following C# code shows how to log events in the .NET client to a text file:

```
var hubConnection = new HubConnection("http://www.contoso.com/");
var writer = new StreamWriter("ClientLog.txt");
writer.AutoFlush = true;
hubConnection.TraceLevel = TraceLevels.All;
hubConnection.TraceWriter = writer;
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await hubConnection.Start();
```

The following output shows entries from the `ClientLog.txt` file for an application using the above configuration file. It shows the client connecting to the server, and the hub invoking a client method called `addMessage`:

```
19:41:39.9103763 - null - ChangeState(Disconnected, Connecting)
19:41:40.3750726 - dd61fd48-d796-4518-b36b-ec1dcb970d72 - WS Connecting to:

19:41:50.3959119 - dd61fd48-d796-4518-b36b-ec1dcb970d72 - WS: OnMessage({})
19:41:50.8928084 - dd61fd48-d796-4518-b36b-ec1dcb970d72 - WS: OnMessage({"C":"d-5196BF5C-A,2|B,0|C,1|D,0","M":
[{"H":"MyHub","M":"addMessage","A":["User Two","Hello!"]}]})
```

Enabling tracing in Windows Phone 8 clients

SignalR applications for Windows Phone apps use the same .NET client as desktop apps, but Console.Out and writing to a file with StreamWriter are not available. Instead, you need to create a custom implementation of TextWriter for tracing.

Logging Windows Phone client events to the UI

The SignalR codebase includes a Windows Phone sample that writes trace output to a TextBlock using a custom TextWriter implementation called `TextBlockWriter`. This class can be found in the

samples/Microsoft.AspNet.SignalR.Client.WP8.Samples project. When creating an instance of `TextBlockWriter`, pass in the current SynchronizationContext, and a StackPanel where it will create a TextBlock to use for trace output:

```
Connection = new HubConnection(ServerURI);
var writer = new TextBlockWriter(SynchronizationContext.Current, StackPanelConsole);
Connection.TraceWriter = writer;
Connection.TraceLevel = TraceLevels.All;
```

The trace output will then be written to a new TextBlock created in the StackPanel you passed in:

Logging Windows Phone client events to the debug console

To send output to the debug console rather than the UI, create an implementation of TextWriter that writes to the debug window, and assign it to your connection's TraceWriter property:

```
Connection = new HubConnection(ServerURI);
var writer = new DebugTextWriter();
Connection.TraceWriter = writer;
Connection.TraceLevel = TraceLevels.All;

...

private class DebugTextWriter : TextWriter
{
    private StringBuilder buffer;

    public DebugTextWriter()
    {
        buffer = new StringBuilder();
    }

    public override void Write(char value)
    {
        switch (value)
        {
            case '\n':
                return;
            case '\r':
                Debug.WriteLine(buffer.ToString());
                buffer.Clear();
                return;
            default:
                buffer.Append(value);
                break;
        }
    }

    public override void Write(string value)
    {
        Debug.WriteLine(value);

    }
    #region implemented abstract members of TextWriter
    public override Encoding Encoding
    {
        get { throw new NotImplementedException(); }
    }
    #endregion
}
```

Trace information will then be written to the debug window in Visual Studio:

Enabling tracing in the JavaScript client

To enable client-side logging on a connection, set the `logging` property on the connection object before you call the `start` method to establish the connection.

Client JavaScript code for enabling tracing to the browser console (with the generated proxy)

```
$.connection.hub.logging = true;
$.connection.hub.start();
```

Client JavaScript code for enabling tracing to the browser console (without the generated proxy)

```
var connection = $.hubConnection();
connection.logging = true;
connection.start();
```

When tracing is enabled, the JavaScript client logs events to the browser console. To access the browser console, see Monitoring Transports.

The following screenshot shows a SignalR JavaScript client with tracing enabled. It shows connection and hub invocation events in the browser console:

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This article describes the security issues you must consider when developing a SignalR application.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This document contains the following sections:

- SignalR Security Concepts
  - Authentication and authorization
  - Connection token
  - Rejoining groups when reconnecting
- How SignalR prevents Cross-Site Request Forgery
- SignalR Security Recommendations
  - Secure Socket Layers (SSL) protocol
  - Do not use groups as a security mechanism
  - Safely handling input from clients
  - Reconciling a change in user status with an active connection
  - Automatically generated JavaScript proxy files
  - Exceptions

SignalR Security Concepts

Authentication and authorization

SignalR does not provide any features for authenticating users. Instead, you integrate the SignalR features into the existing authentication structure for an application. You authenticate users as you would normally in your application, and work with the results of the authentication in your SignalR code. For example, you might authenticate your users with ASP.NET forms authentication, and then in your hub, enforce which users or roles are authorized to call a method. In your hub, you can also pass authentication information, such as user name or whether a user belongs to a role, to the client.

SignalR provides the Authorize attribute to specify which users have access to a hub or method. You apply the Authorize attribute to either a hub or particular methods in a hub. Without the Authorize attribute, all public methods on the hub are available to a client that is connected to the hub. For more information about hubs, see Authentication and Authorization for SignalR Hubs.

You apply the `Authorize` attribute to hubs, but not persistent connections. To enforce authorization rules when using a `PersistentConnection` you must override the `AuthorizeRequest` method. For more information about persistent connections, see Authentication and Authorization for SignalR Persistent Connections.

Connection token

SignalR mitigates the risk of executing malicious commands by validating the identity of the sender. For each request, the client and server pass a connection token which contains the connection id and username for authenticated users. The connection id uniquely identifies each connected client. The server randomly generates the connection id when a new connection is created, and persists that id for the duration of the connection. The authentication mechanism for the web application provides the username. SignalR uses encryption and a digital signature to protect the connection token.

For each request, the server validates the contents of the token to ensure that the request is coming from the specified user. The username must correspond to the connection id. By validating both the connection id and the username, SignalR prevents a malicious user from easily impersonating another user. If the server cannot validate the connection token, the request fails.

Because the connection id is part of the verification process, you should not reveal one user's connection id to other users or store the value on the client, such as in a cookie.

Connection tokens vs. other token types

Connection tokens are occasionally flagged by security tools because they appear to be session tokens or authentication tokens, which poses a risk if exposed.

SignalR's connection token isn't an authentication token. It is used to confirm that the user making this request is the same one that created the connection. The connection token is necessary because ASP.NET SignalR allows connections to move between servers. The token associates the connection with a particular user but doesn't assert the identity of the user making the request. For a SignalR request to be properly authenticated, it must have some other token that asserts the identity of the user, such as a cookie or bearer token. However, the connection token itself makes no claim that the request was made by that user, only that the connection ID contained within the token is associated with that user.

Since the connection token provides no authentication claim of its own, it isn't considered a "session" or "authentication" token. Taking a given user's connection token and replaying it in a request authenticated as a different user (or an unauthenticated request) will fail, because the user identity of the request and the identity stored in the token won't match.

Rejoining groups when reconnecting

By default, the SignalR application will automatically re-assign a user to the appropriate groups when reconnecting from a temporary disruption, such as when a connection is dropped and re-established before the connection times out. When reconnecting, the client passes a group token that includes the connection id and the assigned groups. The group token is digitally signed and encrypted. The client retains the same connection id after a reconnection; therefore, the connection id passed from the reconnected client must match the previous connection id used by the client. This verification prevents a malicious user from passing requests to join unauthorized groups when reconnecting.

However, it's important to note, that the group token does not expire. If a user belonged to a group in the past, but was banned from that group, that user may be able to mimic a group token that includes the prohibited group. If you need to securely manage which users belong to which groups, you need to store that data on the server, such as in a database. Then, add logic to your application that verifies on the server whether a user belongs to a group. For an example of verifying group membership, see Working with groups.

Automatically rejoining groups only applies when a connection is reconnected after a temporary disruption. If a user disconnects by navigating away from the application or the application restarts, your application must handle how to add that user to the correct groups. For more information, see Working with groups.

How SignalR prevents Cross-Site Request Forgery

Cross-Site Request Forgery (CSRF) is an attack where a malicious site sends a request to a vulnerable site where the user is currently logged in. SignalR prevents CSRF by making it extremely unlikely for a malicious site to create a valid request for your SignalR application.

Description of CSRF attack

Here is an example of a CSRF attack:

1. A user logs into www.example.com, using forms authentication.
2. The server authenticates the user. The response from the server includes an authentication cookie.
3. Without logging out, the user visits a malicious web site. This malicious site contains the following HTML form:

   ```
   <h1>You Are a Winner!</h1>
   <form action="http://example.com/api/account" method="post">
       <input type="hidden" name="Transaction" value="withdraw" />
       <input type="hidden" name="Amount" value="1000000" />
       <input type="submit" value="Click Me"/>
   </form>
   ```

   Notice that the form action posts to the vulnerable site, not to the malicious site. This is the "cross-site" part of CSRF.
4. The user clicks the submit button. The browser includes the authentication cookie with the request.
5. The request runs on the example.com server with the user's authentication context, and can do anything that an authenticated user is allowed to do.

Although this example requires the user to click the form button, the malicious page could just as easily run a script that sends an AJAX request to your SignalR application. Moreover, using SSL does not prevent a CSRF attack, because the malicious site can send an "https://" request.

Typically, CSRF attacks are possible against web sites that use cookies for authentication, because browsers send all relevant cookies to the destination web site. However, CSRF attacks are not limited to exploiting cookies. For example, Basic and Digest authentication are also vulnerable. After a user logs in with Basic or Digest authentication, the browser automatically sends the credentials until the session ends.

CSRF mitigations taken by SignalR

SignalR takes the following steps to prevent a malicious site from creating valid requests to your application. SignalR takes these steps by default, you do not need to take any action in your code.

- **Disable cross domain requests** SignalR disables cross domain requests to prevent users from calling a SignalR endpoint from an external domain. SignalR considers any request from an external domain to be invalid and blocks the request. We recommend that you keep this default behavior; otherwise, a malicious site could trick users into sending commands to your site. If you need to use cross domain requests, see How to establish a cross-domain connection .
- **Pass connection token in query string, not cookie** SignalR passes the connection token as a query string value, instead of as a cookie. Storing the connection token in a cookie is unsafe because the browser can inadvertently forward the connection token when malicious code is encountered. Also, passing the connection token in the query string prevents the connection token from persisting beyond the current connection. Therefore, a malicious user cannot make a request under another user's authentication credentials.
- **Verify connection token** As described in the Connection token section, the server knows which connection id is associated with each authenticated user. The server does not process any request from a connection id that does not match the user name. It is unlikely a malicious user could guess a valid request because the malicious user would have to know the user name and the current randomly-generated connection id. That connection id becomes invalid as soon as the connection is ended. Anonymous users should not have access to any sensitive information.

SignalR Security Recommendations

Secure Socket Layers (SSL) protocol

The SSL protocol uses encryption to secure the transport of data between a client and server. If your SignalR application transmits sensitive information between the client and server, use SSL for the transport. For more information about setting up SSL, see How to set up SSL on IIS 7.

Do not use groups as a security mechanism

Groups are a convenient way of collecting related users, but they are not a secure mechanism for limiting access to sensitive information. This is especially true when users can automatically rejoin groups during a reconnect. Instead, consider adding privileged users to a role and limiting access to a hub method to only members of that role. For an example of restricting access based on a role, see Authentication and Authorization for SignalR Hubs. For an example of checking user access to groups when reconnecting, see Working with groups.

Safely handling input from clients

To ensure that a malicious user does not send script to other users, you must encode all input from clients that is intended for broadcast to other clients. You should encode messages on the receiving clients rather than the server, because your SignalR application may have many different types of clients. Therefore, HTML-encoding works for a web client, but not for other types of clients. For example, a web client method to display a chat message would safely handle the user name and message by calling the `html()` function.

```
chat.client.addMessageToPage = function (name, message) {
    // Html encode display name and message.
    var encodedName = $('<div />').text(name).html();
    var encodedMsg = $('<div />').text(message).html();
    // Add the message to the page.
    $('#discussion').append('<li><strong>' + encodedName
        + '</strong>:  ' + encodedMsg + '</li>');
};
```

Reconciling a change in user status with an active connection

If a user's authentication status changes while an active connection exists, the user will receive an error that states, "The user identity cannot change during an active SignalR connection." In that case, your application should re-connect to the server to make sure the connection id and username are coordinated. For example, if your application allows the user to log out while an active connection exists, the username for the connection will no longer match the name that is passed in for the next request. You will want to stop the connection before the user logs out, and then restart it.

However, it is important to note that most applications will not need to manually stop and start the connection. If your application redirects users to a separate page after logging out, such as the default behavior in a Web Forms application or MVC application, or refreshes the current page after logging out, the active connection is automatically disconnected and does not require any additional action.

The following example shows how to stop and start a connection when the user status has changed.

```
<script type="text/javascript">
    $(function () {
        var chat = $.connection.sampleHub;
        $.connection.hub.start().done(function () {
            $('#logoutbutton').click(function () {
                chat.connection.stop();
                $.ajax({
                    url: "Services/SampleWebService.svc/LogOut",
                    type: "POST"
                }).done(function () {
                    chat.connection.start();
                });
            });
        });
    });
</script>
```

Or, the user's authentication status may change if your site uses sliding expiration with Forms Authentication, and there is no activity to keep the authentication cookie valid. In that case, the user will be logged out and the user name will no longer match the user name in the connection token. You can fix this problem by adding some script that periodically requests a resource on the web server to keep the authentication cookie valid. The following example shows how to request a resource every 30 minutes.

```
$(function () {
    setInterval(function() {
        $.ajax({
            url: "Ping.aspx",
            cache: false
        });
    }, 1800000);
});
```

Automatically generated JavaScript proxy files

If you do not want to include all of the hubs and methods in the JavaScript proxy file for each user, you can disable the automatic generation of the file. You might choose this option if you have multiple hubs and methods, but do not want every user to be aware of all of the methods. You disable automatic generation by setting `EnableJavaScriptProxies` to `false`.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableJavaScriptProxies = false;
app.MapSignalR(hubConfiguration);
```

For more information about the JavaScript proxy files, see The generated proxy and what it does for you.

Exceptions

You should avoid passing exception objects to clients because the objects may expose sensitive information to the clients. Instead, call a method on the client that displays the relevant error message.

```
public Task SampleMethod()
{
    try
    {
        // code that can throw an exception
    }
    catch(Exception e)
    {
        // add code to log exception and take remedial steps

        return Clients.Caller.DisplayError("Sorry, the request could not be processed.");
    }
}
```

Authentication and Authorization for SignalR Hubs

2/20/2020 • 7 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to restrict which users or roles can access hub methods.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This topic contains the following sections:

- Authorize attribute
- Require authentication for all hubs
- Customized authorization
- Pass authentication information to clients
- Authentication options for .NET clients
  - Cookie with Forms Authentication
  - Windows Authentication
  - Connection header
  - Certificate

Authorize attribute

SignalR provides the Authorize attribute to specify which users or roles have access to a hub or method. This attribute is located in the `Microsoft.AspNet.SignalR` namespace. You apply the `Authorize` attribute to either a hub or particular methods in a hub. When you apply the `Authorize` attribute to a hub class, the specified

authorization requirement is applied to all of the methods in the hub. This topic provides examples of the different types of authorization requirements that you can apply. Without the `Authorize` attribute, a connected client can access any public method on the hub.

If you have defined a role named "Admin" in your web application, you could specify that only users in that role can access a hub with the following code.

```
[Authorize(Roles = "Admin")]
public class AdminAuthHub : Hub
{
}
```

Or, you can specify that a hub contains one method that is available to all users, and a second method that is only available to authenticated users, as shown below.

```
public class SampleHub : Hub
{
    public void UnrestrictedSend(string message){ . . . }

    [Authorize]
    public void AuthenticatedSend(string message){ . . . }
}
```

The following examples address different authorization scenarios:

- `[Authorize]` – only authenticated users
- `[Authorize(Roles = "Admin,Manager")]` – only authenticated users in the specified roles
- `[Authorize(Users = "user1,user2")]` – only authenticated users with the specified user names
- `[Authorize(RequireOutgoing=false)]` – only authenticated users can invoke the hub, but calls from the server back to clients are not limited by authorization, such as, when only certain users can send a message but all others can receive the message. The RequireOutgoing property can only be applied to the entire hub, not on individuals methods within the hub. When RequireOutgoing is not set to false, only users that meet the authorization requirement are called from the server.

Require authentication for all hubs

You can require authentication for all hubs and hub methods in your application by calling the RequireAuthentication method when the application starts. You might use this method when you have multiple hubs and want to enforce an authentication requirement for all of them. With this method, you cannot specify requirements for role, user, or outgoing authorization. You can only specify that access to the hub methods is restricted to authenticated users. However, you can still apply the Authorize attribute to hubs or methods to specify additional requirements. Any requirement you specify in an attribute is added to the basic requirement of authentication.

The following example shows a Startup file which restricts all hub methods to authenticated users.

```
public partial class Startup {
    public void Configuration(IAppBuilder app) {
        app.MapSignalR();
        GlobalHost.HubPipeline.RequireAuthentication();
    }
}
```

If you call the `RequireAuthentication()` method after a SignalR request has been processed, SignalR will throw a `InvalidOperationException` exception. SignalR throws this exception because you cannot add a module to the

HubPipeline after the pipeline has been invoked. The previous example shows calling the `RequireAuthentication` method in the `Configuration` method which is executed one time prior to handling the first request.

Customized authorization

If you need to customize how authorization is determined, you can create a class that derives from `AuthorizeAttribute` and override the UserAuthorized method. For each request, SignalR invokes this method to determine whether the user is authorized to complete the request. In the overridden method, you provide the necessary logic for your authorization scenario. The following example shows how to enforce authorization through claims-based identity.

```
[AttributeUsage(AttributeTargets.Class, Inherited = false, AllowMultiple = false)]
public class AuthorizeClaimsAttribute : AuthorizeAttribute
{
    protected override bool UserAuthorized(System.Security.Principal.IPrincipal user)
    {
        if (user == null)
        {
            throw new ArgumentNullException("user");
        }

        var principal = user as ClaimsPrincipal;

        if (principal != null)
        {
            Claim authenticated = principal.FindFirst(ClaimTypes.Authentication);
            if (authenticated != null && authenticated.Value == "true")
            {
                return true;
            }
            else
            {
                return false;
            }
        }
        else
        {
            return false;
        }
    }
}
```

Pass authentication information to clients

You may need to use authentication information in the code that runs on the client. You pass the required information when calling the methods on the client. For example, a chat application method could pass as a parameter the user name of the person posting a message, as shown below.

```
public Task SendChatMessage(string message)
{
    string name;
    var user = Context.User;

    if (user.Identity.IsAuthenticated)
    {
        name = user.Identity.Name;
    }
    else
    {
        name = "anonymous";
    }
    return Clients.All.addMessageToPage(name, message);
}
```

Or, you can create an object to represent the authentication information and pass that object as a parameter, as shown below.

```
public class SampleHub : Hub
{
    public override Task OnConnected()
    {
        return Clients.All.joined(GetAuthInfo());
    }

    protected object GetAuthInfo()
    {
        var user = Context.User;
        return new
        {
            IsAuthenticated = user.Identity.IsAuthenticated,
            IsAdmin = user.IsInRole("Admin"),
            UserName = user.Identity.Name
        };
    }
}
```

You should never pass one client's connection id to other clients, as a malicious user could use it to mimic a request from that client.

Authentication options for .NET clients

When you have a .NET client, such as a console app, which interacts with a hub that is limited to authenticated users, you can pass the authentication credentials in a cookie, the connection header, or a certificate. The examples in this section show how to use those different methods for authenticating a user. They are not fully-functional SignalR apps. For more information about .NET clients with SignalR, see Hubs API Guide - .NET Client.

Cookie

When your .NET client interacts with a hub that uses ASP.NET Forms Authentication, you will need to manually set the authentication cookie on the connection. You add the cookie to the `CookieContainer` property on the HubConnection object. The following example shows a console app that retrieves an authentication cookie from a web page and adds that cookie to the connection.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        Cookie returnedCookie;

        Console.Write("Enter user name: ");
        string username = Console.ReadLine();

        Console.Write("Enter password: ");
        string password = Console.ReadLine();

        var authResult = AuthenticateUser(username, password, out returnedCookie);

        if (authResult)
        {
            connection.CookieContainer = new CookieContainer();
            connection.CookieContainer.Add(returnedCookie);
            Console.WriteLine("Welcome " + username);
        }
        else
        {
            Console.WriteLine("Login failed");
        }
    }

    private static bool AuthenticateUser(string user, string password, out Cookie authCookie)
    {
        var request = WebRequest.Create("https://www.contoso.com/RemoteLogin") as HttpWebRequest;
        request.Method = "POST";
        request.ContentType = "application/x-www-form-urlencoded";
        request.CookieContainer = new CookieContainer();

        var authCredentials = "UserName=" + user + "&Password=" + password;
        byte[] bytes = System.Text.Encoding.UTF8.GetBytes(authCredentials);
        request.ContentLength = bytes.Length;
        using (var requestStream = request.GetRequestStream())
        {
            requestStream.Write(bytes, 0, bytes.Length);
        }

        using (var response = request.GetResponse() as HttpWebResponse)
        {
            authCookie = response.Cookies[FormsAuthentication.FormsCookieName];
        }

        if (authCookie != null)
        {
            return true;
        }
        else
        {
            return false;
        }
    }
}
```

The console app posts the credentials to **www.contoso.com/RemoteLogin** which could refer to an empty page that contains the following code-behind file.

```
using System;
using System.Web.Security;

namespace SignalRWithConsoleChat
{
    public partial class RemoteLogin : System.Web.UI.Page
    {
        protected void Page_Load(object sender, EventArgs e)
        {
            string username = Request["UserName"];
            string password = Request["Password"];
            bool result = Membership.ValidateUser(username, password);
            if (result)
            {
                FormsAuthentication.SetAuthCookie(username, false);
            }
        }
    }
}
```

Windows authentication

When using Windows authentication, you can pass the current user's credentials by using the DefaultCredentials property. You set the credentials for the connection to the value of the DefaultCredentials.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        connection.Credentials = CredentialCache.DefaultCredentials;
        connection.Start().Wait();
    }
}
```

Connection header

If your application is not using cookies, you can pass user information in the connection header. For example, you can pass a token in the connection header.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        connection.Headers.Add("myauthtoken", /* token data */);
        connection.Start().Wait();
    }
}
```

Then, in the hub, you would verify the user's token.

Certificate

You can pass a client certificate to verify the user. You add the certificate when creating the connection. The following example shows only how to add a client certificate to the connection; it does not show the full console app. It uses the X509Certificate class which provides several different ways to create the certificate.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        connection.AddClientCertificate(X509Certificate.CreateFromCertFile("MyCert.cer"));
        connection.Start().Wait();
    }
}
```

Authentication and Authorization for SignalR Persistent Connections

2/20/2020 • 2 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to enforce authorization on a persistent connection. For general information about integrating security into a SignalR application, see Introduction to Security.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Enforce authorization

To enforce authorization rules when using a PersistentConnection you must override the `AuthorizeRequest` method. You cannot use the `Authorize` attribute with persistent connections. The `AuthorizeRequest` method is called by the SignalR Framework before every request to verify that the user is authorized to perform the requested action. The `AuthorizeRequest` method is not called from the client; instead, you authenticate the user through your application's standard authentication mechanism.

The example below shows how to limit requests to authenticated users.

```
public class AuthenticatedConnection : PersistentConnection
{
    protected override bool AuthorizeRequest(IRequest request)
    {
        return request.User.Identity.IsAuthenticated;
    }
}
```

You can add any customized authorization logic in the AuthorizeRequest method; such as, checking whether a user belongs to a particular role.

SignalR Performance

2/20/2020 • 10 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to design for, measure, and improve performance in a SignalR application.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

For a recent presentation on SignalR performance and scaling, see Scaling the Real-time Web with ASP.NET SignalR.

This topic contains the following sections:

- Design considerations
- Tuning your SignalR server for performance
- Troubleshooting performance issues
- Using SignalR performance counters
- Using other performance counters
- Other resources

Design considerations

This section describes patterns that can be implemented during the design of a SignalR application, to ensure that performance is not being hindered by generating unnecessary network traffic.

Throttling message frequency

Even in an application that sends out messages at a high frequency (such as a realtime gaming application), most applications don't need to send more than a few messages a second. To reduce the amount of traffic that each client generates, a message loop can be implemented that queues and sends out messages no more frequently than a fixed rate (that is, up to a certain number of messages will be sent every second, if there are messages in

that time interval to be sent). For a sample application that throttles messages to a certain rate (from both client and server), see High-Frequency Realtime with SignalR.

Reducing message size

You can reduce the size of a SignalR message by reducing the size of your serialized objects. In server code, if you're sending an object that contains properties that don't need to be transmitted, prevent those properties from being serialized by using the `JsonIgnore` attribute. The names of properties are also stored in the message; the names of properties can be shortened using the `JsonProperty` attribute. The following code sample demonstrates how to exclude a property from being sent to the client, and how to shorten property names:

.NET server code that demonstrates the JsonIgnore attribute to exclude data from being sent to the client, and the JsonProperty attribute to reduce message size

```
using Newtonsoft.Json;
using System;
public class ShapeModel
{
    [JsonProperty("l")]
    public double Left { get; set; }
    [JsonProperty("t")]
    public double Top { get; set; }
    // We don't want the client to get the "LastUpdatedBy" property
    [JsonIgnore]
    public string LastUpdatedBy { get; set; }
}
```

In order to retain readability/ maintainability in the client code, the abbreviated property names can be remapped to human-friendly names after the message is received. The following code sample demonstrates one possible way of remapping shortened names to longer ones, by defining a message contract (mapping), and using the `reMap` function to apply the contract to the optimized message class:

Client-side JavaScript code that remaps shortened property names to human-readable names

```
function reMap(smallObject, contract) {
    var largeObject = {};
    for (var smallProperty in contract) {
        largeObject[contract[smallProperty]] = smallObject[smallProperty];
    }
    return largeObject;
}
var shapeModelContract = {
    l: "left",
    t: "top"
};
myHub.client.setShape = function (shapeModelSmall) {
    var shapeModel = reMap(shapeModelSmall, shapeModelContract);
    // shapeModelSmall has "l" and "t" properties  but after remapping
    // shapeModel now has "left" and "top" properties
};
```

Names can be shortened in messages from the client to the server as well, using the same method.

Reducing the memory footprint (that is, the amount of memory used for the message) of the message object can also improve performance. For example, if the full range of an `int` is not needed, a `short` or `byte` can be used instead.

Since messages are stored in the message bus in server memory, reducing the size of messages can also address server memory issues.

Tuning your SignalR server for performance

The following configuration settings can be used to tune your server for better performance in a SignalR application. For general information on how to improve performance in an ASP.NET application, see Improving ASP.NET Performance.

SignalR configuration settings

- **DefaultMessageBufferSize**: By default, SignalR retains 1000 messages in memory per hub per connection. If large messages are being used, this may create memory issues which can be alleviated by reducing this value. This setting can be set in the `Application_Start` event handler in an ASP.NET application, or in the `Configuration` method of an OWIN startup class in a self-hosted application. The following sample demonstrates how to reduce this value in order to reduce the memory footprint of your application in order to reduce the amount of server memory used:

  .NET server code in Startup.cs for decreasing default message buffer size

  ```
  public class Startup
  {
      public void Configuration(IAppBuilder app)
      {
          // Any connection or hub wire up and configuration should go here
          GlobalHost.Configuration.DefaultMessageBufferSize = 500;
          app.MapSignalR();
      }
  }
  ```

IIS configuration settings

- **Max concurrent requests per application**: Increasing the number of concurrent IIS requests will increase server resources available for serving requests. The default value is 5000; to increase this setting, execute the following commands in an elevated command prompt:

  ```
  cd %windir%\System32\inetsrv\
  appcmd.exe set config /section:system.webserver/serverRuntime
          /appConcurrentRequestLimit:10000
  ```

- **ApplicationPool QueueLength**: This is the maximum number of requests that Http.sys queues for the application pool. When the queue is full, new requests receive a 503 "Service Unavailable" response. The default value is 1000.

  Shortening the queue length for the worker process in the application pool hosting your application will conserve memory resources. For more information, see Managing, Tuning, and Configuring Application Pools.

ASP.NET configuration settings

This section includes configuration settings that can be set in the `aspnet.config` file. This file is found in one of two locations, depending on platform:

- `%windir%\Microsoft.NET\Framework\v4.0.30319\aspnet.config`
- `%windir%\Microsoft.NET\Framework64\v4.0.30319\aspnet.config`

ASP.NET settings that may improve SignalR performance include the following:

- **Maximum concurrent requests per CPU**: Increasing this setting may alleviate performance bottlenecks. To increase this setting, add the following configuration setting to the `aspnet.config` file:

```
<?xml version="1.0" encoding="UTF-8" ?>
<configuration>
    <system.web>
        <applicationPool maxConcurrentRequestsPerCPU="20000" />
    </system.web>
</configuration>
```

- **Request Queue Limit**: When the total number of connections exceeds the `maxConcurrentRequestsPerCPU` setting, ASP.NET will start throttling requests using a queue. To increase the size of the queue, you can increase the `requestQueueLimit` setting. To do this, add the following configuration setting to the `processModel` node in `config/machine.config` (rather than `aspnet.config`):

```
<processModel autoConfig="false" requestQueueLimit="250000" />
```

Troubleshooting performance issues

This section describes ways to find performance bottlenecks in your application.

Verifying that WebSocket is being used

While SignalR can use a variety of transports for communication between client and server, WebSocket offers a significant performance advantage, and should be used if the client and server support it. To determine if your client and server meet the requirements for WebSocket, see Transports and Fallbacks. To determine what transport is being used in your application, you can use the browser developer tools, and examine the logs to see what transport is being used for the connection. For information on using the browser development tools in Internet Explorer and Chrome, see Transports and Fallbacks.

Using SignalR performance counters

This section describes how to enable and use SignalR performance counters, found in the `Microsoft.AspNet.SignalR.Utils` package.

Installing signalr.exe

Performance counters can be added to the server using a utility called SignalR.exe. To install this utility, follow these steps:

1. In Visual Studio, select **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution**
2. Search for **signalr.utils**, and select Install.

3. Accept the license agreement to install the package.
4. SignalR.exe will be installed to `<project folder>/packages/Microsoft.AspNet.SignalR.Utils.<version>/tools`.

Installing performance counters with SignalR.exe

To install SignalR performance counters, run SignalR.exe in an elevated command prompt with the following parameter:

```
SignalR.exe ipc
```

To remove SignalR performance counters, run SignalR.exe in an elevated command prompt with the following parameter:

```
SignalR.exe upc
```

SignalR Performance counters

The utilities package installs the following performance counters. The "Total" counters measure the number of events since the last application pool or server restart.

Connection metrics

The following metrics measure the connection lifetime events that occur. For more information, see Understanding and Handling Connection Lifetime Events.

- **Connections Connected**
- **Connections Reconnected**
- **Connections Disconnected**
- **Connections Current**

Message metrics

The following metrics measure the message traffic generated by SignalR.

- **Connection Messages Received Total**
- **Connection Messages Sent Total**
- **Connection Messages Received/Sec**
- **Connection Messages Sent/Sec**

Message bus metrics

The following metrics measure traffic through the internal SignalR message bus, the queue in which all incoming and outgoing SignalR messages are placed. A message is **Published** when it is sent or broadcast. A **Subscriber** in this context is a subscription on the message bus; this should equal the number of clients plus the server itself. An **Allocated Worker** is a component that sends data to active connections; a **Busy Worker** is one that is actively sending a message.

- **Message Bus Messages Received Total**
- **Message Bus Messages Received/Sec**
- **Message Bus Messages Published Total**
- **Message Bus Messages Published/Sec**
- **Message Bus Subscribers Current**
- **Message Bus Subscribers Total**
- **Message Bus Subscribers/Sec**
- **Message Bus Allocated Workers**
- **Message Bus Busy Workers**
- **Message Bus Topics Current**

Error metrics

The following metrics measure errors generated by SignalR message traffic. **Hub Resolution** errors occur when a hub or hub method cannot be resolved. **Hub Invocation** errors are exceptions thrown while invoking a hub

method. **Transport** errors are connection errors thrown during an HTTP request or response.

- **Errors: All Total**
- **Errors: All/Sec**
- **Errors: Hub Resolution Total**
- **Errors: Hub Resolution/Sec**
- **Errors: Hub Invocation Total**
- **Errors: Hub Invocation/Sec**
- **Errors: Transport Total**
- **Errors: Transport/Sec**

Scaleout metrics

The following metrics measure traffic and errors generated by the scaleout provider. A **Stream** in this context is a scale unit used by the scaleout provider; this is a table if SQL Server is used, a Topic if Service Bus is used, and a Subscription if Redis is used. Each stream ensures ordered read and write operations; a single stream is a potential scale bottleneck, so the number of streams can be increased to help reduce that bottleneck. If multiple streams are used, SignalR will automatically distribute (shard) messages across these streams in a way that ensures messages sent from any given connection are in order.

The MaxQueueLength setting controls the length of the scaleout send queue maintained by SignalR. Setting it to a value greater than 0 will place all messages in a send queue to be sent one at a time to the configured messaging backplane. If the size of the queue goes above the configured length, subsequent calls to send will fail immediately with an InvalidOperationException until the number of messages in the queue is less than the setting again. Queueing is disabled by default because the implemented backplanes generally have their own queuing or flow-control in place. In the case of SQL Server, connection pooling effectively limits the number of sends going on at any one time.

By default, only one stream is used for SQL Server and Redis, five streams are used for Service Bus, and queueing is disabled, but these settings can be changed through configuration on SQL Server and Service Bus:

.NET Server Code for configuring table count and queue length for SQL Server backplane

```
var connectionString = "(your connection string)";
var config = new SqlScaleoutConfiguration(connectionString) {
TableCount = 3,
MaxQueueLength = 50 };
GlobalHost.DependencyResolver.UseSqlServer(config);
```

.NET Server Code for configuring topic count and queue length for Service Bus backplane

```
string connectionString = "(your connection string)";
var config = new ServiceBusScaleoutConfiguration(connectionString, "YourAppName") {
TopicCount = 3,
MaxQueueLength = 50 };
GlobalHost.DependencyResolver.UseServiceBus(config);
```

A **Buffering** stream is one that has entered a faulted state; when the stream is in the faulted state, all messages sent to the backplane will fail immediately until the stream is no longer faulting. The **Send Queue Length** is the number of messages that have been posted but not yet sent.

- **Scaleout Message Bus Messages Received/Sec**
- **Scaleout Streams Total**
- **Scaleout Streams Open**
- **Scaleout Streams Buffering**

- **Scaleout Errors Total**
- **Scaleout Errors/Sec**
- **Scaleout Send Queue Length**

For more information on what these counters are measuring, see SignalR Scaleout with Azure Service Bus.

Using other performance counters

The following performance counters may also be useful in monitoring your application's performance.

Memory

- .NET CLR Memory\# bytes in all Heaps (for w3wp)

ASP.NET

- ASP.NET\Requests Current
- ASP.NET\Queued
- ASP.NET\Rejected

CPU

- Processor Information\Processor Time

TCP/IP

- TCPv6/Connections Established
- TCPv4/Connections Established

Web Service

- Web Service\Current Connections
- Web Service\Maximum Connections

Threading

- .NET CLR Locks And Threads\# of current logical Threads
- .NET CLR Locks And Threads\# of current physical Threads

Other Resources

For more information on ASP.NET performance monitoring and tuning, see the following topics:

- ASP.NET Performance Overview
- ASP.NET Thread Usage on IIS 7.5, IIS 7.0, and IIS 6.0
- <applicationPool> Element (Web Settings)

Introduction to Scaleout in SignalR

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

In general, there are two ways to scale a web application: *scale up* and *scale out*.

- Scale up means using a larger server (or a larger VM) with more RAM, CPUs, etc.
- Scale out means adding more servers to handle the load.

The problem with scaling up is that you quickly hit a limit on the size of the machine. Beyond that, you need to scale out. However, when you scale out, clients can get routed to different servers. A client that is connected to one server will not receive messages sent from another server.

One solution is to forward messages between servers, using a component called a *backplane*. With a backplane enabled, each application instance sends messages to the backplane, and the backplane forwards them to the

other application instances. (In electronics, a backplane is a group of parallel connectors. By analogy, a SignalR backplane connects multiple servers.)

SignalR currently provides three backplanes:

- **Azure Service Bus**. Service Bus is a messaging infrastructure that allows components to send messages in a loosely coupled way.
- **Redis**. Redis is an in-memory key-value store. Redis supports a publish/subscribe ("pub/sub") pattern for sending messages.
- **SQL Server**. The SQL Server backplane writes messages to SQL tables. The backplane uses Service Broker for efficient messaging. However, it also works if Service Broker is not enabled.

If you deploy your application on Azure, consider using the Redis backplane using Azure Redis Cache. If you are deploying to your own server farm, consider the SQL Server or Redis backplanes.

The following topics contain step-by-step tutorials for each backplane:

- SignalR Scaleout with Azure Service Bus
- SignalR Scaleout with Redis
- SignalR Scaleout with SQL Server

Implementation

In SignalR, every message is sent through a message bus. A message bus implements the IMessageBus interface, which provides a publish/subscribe abstraction. The backplanes work by replacing the default **IMessageBus** with a bus designed for that backplane. For example, the message bus for Redis is RedisMessageBus, and it uses the Redis pub/sub mechanism to send and receive messages.

Each server instance connects to the backplane through the bus. When a message is sent, it goes to the backplane, and the backplane sends it to every server. When a server gets a message from the backplane, it puts the message in its local cache. The server then delivers messages to clients from its local cache.

For each client connection, the client's progress in reading the message stream is tracked using a cursor. (A cursor represents a position in the message stream.) If a client disconnects and then reconnects, it asks the bus for any messages that arrived after the client's cursor value. The same thing happens when a connection uses long polling. After a long poll request completes, the client opens a new connection and asks for messages that arrived after the cursor.

The cursor mechanism works even if a client is routed to a different server on reconnect. The backplane is aware of all the servers, and it doesn't matter which server a client connects to.

Limitations

Using a backplane, the maximum message throughput is lower than it is when clients talk directly to a single server node. That's because the backplane forwards every message to every node, so the backplane can become a bottleneck. Whether this limitation is a problem depends on the application. For example, here are some typical SignalR scenarios:

- Server broadcast (e.g., stock ticker): Backplanes work well for this scenario, because the server controls the rate at which messages are sent.
- Client-to-client (e.g., chat): In this scenario, the backplane might be a bottleneck if the number of messages scales with the number of clients; that is, if the rate of messages grows proportionally as more clients join.
- High-frequency realtime (e.g., real-time games): A backplane is not recommended for this scenario.

Enabling Tracing For SignalR Scaleout

To enable tracing for the backplanes, add the following sections to the web.config file, under the root **configuration** element:

```
<configuration>
  <system.diagnostics>
    <sources>
      <source name="SignalR.SqlMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.ServiceBusMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.ScaleoutMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
    </sources>
    <switches>
      <add name="SignalRSwitch" value="Verbose" />
      <!-- Off, Critical, Error, Warning, Information, Verbose -->
    </switches>
    <sharedListeners>
      <add name="SignalR-Bus"
          type="System.Diagnostics.TextWriterTraceListener"
          initializeData="bus.log.txt" />
    </sharedListeners>
    <trace autoflush="true" />
  </system.diagnostics>
  . . .
</configuration>
```

SignalR Scaleout with Azure Service Bus

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

In this tutorial, you will deploy a SignalR application to a Windows Azure Web Role, using the Service Bus backplane to distribute messages to each role instance. (You can also use the Service Bus backplane with web apps in Azure App Service.)

Prerequisites:

- A Windows Azure account.
- The Windows Azure SDK.
- Visual Studio 2012 or 2013.

The service bus backplane is also compatible with Service Bus for Windows Server, version 1.1. However, it is not compatible with version 1.0 of Service Bus for Windows Server.

Pricing

The Service Bus backplane uses topics to send messages. For the latest pricing information, see Service Bus. At the time of this writing, you can send 1,000,000 messages per month for less than $1. The backplane sends a service bus message for each invocation of a SignalR hub method. There are also some control messages for connections, disconnections, joining or leaving groups, and so forth. In most applications, the majority of the message traffic will be hub method invocations.

Overview

Before we get to the detailed tutorial, here is a quick overview of what you will do.

1. Use the Windows Azure portal to create a new Service Bus namespace.

2. Add these NuGet packages to your application:

- Microsoft.AspNet.SignalR
- Microsoft.AspNet.SignalR.ServiceBus3 or Microsoft.AspNet.SignalR.ServiceBus

3. Create a SignalR application.

4. Add the following code to Startup.cs to configure the backplane:

```
public void Configuration(IAppBuilder app)
{
    string connectionString = "Service Bus connection string";
    GlobalHost.DependencyResolver.UseServiceBus(connectionString, "YourAppName");

    app.MapSignalR();
    // ...
}
```

This code configures the backplane with the default values for TopicCount and MaxQueueLength. For information on changing these values, see SignalR Performance: Scaleout Metrics.

For each application, pick a different value for "YourAppName". Do not use the same value across multiple applications.

Create the Azure Services

Create a Cloud Service, as described in How to Create and Deploy a Cloud Service. Follow the steps in the section "How to: Create a cloud service using Quick Create". For this tutorial, you do not need to upload a certificate.

Create a new Service Bus namespace, as described in How to Use Service Bus Topics/Subscriptions. Follow the steps in the section "Create a Service Namespace".

> **NOTE**
>
> Make sure to select the same region for the cloud service and the Service Bus namespace.

Create the Visual Studio Project

Start Visual Studio. From the **File** menu, click **New Project**.

In the **New Project** dialog box, expand **Visual C#**. Under **Installed Templates**, select **Cloud** and then select **Windows Azure Cloud Service**. Keep the default .NET Framework 4.5. Name the application ChatService and click **OK**.

In the **New Windows Azure Cloud Service** dialog, select ASP.NET Web Role. Click the right-arrow button (>) to add the role to your solution.

Hover the mouse over the new role, so the pencil icon visible. Click this icon to rename the role. Name the role "SignalRChat" and click **OK**.

In the **New ASP.NET Project** dialog, select **MVC**, and click OK.

The project wizard creates two projects:

- ChatService: This project is the Windows Azure application. It defines the Azure roles and other configuration options.
- SignalRChat: This project is your ASP.NET MVC 5 project.

Create the SignalR Chat Application

To create the chat application, follow the steps in the tutorial Getting Started with SignalR and MVC 5.

Use NuGet to install the required libraries. From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the **Package Manager Console** window, enter the following commands:

```
Install-Package -ProjectName SignalRChat Microsoft.AspNet.SignalR
Install-Package -ProjectName SignalRChat Microsoft.AspNet.SignalR.ServiceBus
```

Use the `-ProjectName` option to install the packages to the ASP.NET MVC project, rather than the Windows Azure project.

Configure the Backplane

In your application's Startup.cs file, add the following code:

```
public void Configuration(IAppBuilder app)
{
    // Any connection or hub wire up and configuration should go here
    string connectionString = "";
    GlobalHost.DependencyResolver.UseServiceBus(connectionString, "Chat");

    app.MapSignalR();
}
```

Now you need to get your service bus connection string. In the Azure portal, select the service bus namespace that you created and click the Access Key icon.

Copy the connection string to the clipboard, then paste it into the *connectionString* variable.

```
string connectionString = "Endpoint=sb://xxxx.servicebus.windows.net/;
SharedSecretIssuer=owner;SharedSecretValue=XXXXXXXX";
```

Deploy to Azure

In Solution Explorer, expand the **Roles** folder inside the ChatService project.

Right-click the SignalRChat role and select **Properties**. Select the **Configuration** tab. Under **Instances** select 2. You can also set the VM size to **Extra Small**.

Save the changes.

In Solution Explorer, right-click the ChatService project. Select **Publish**.

If this is your first time publishing to Windows Azure, you must download your credentials. In the **Publish** wizard, click "Sign in to download credentials". This will prompt you to sign into the Windows Azure portal and download a publish settings file.

Click **Import** and select the publish settings file that you downloaded.

Click **Next**. In the **Publish Settings** dialog, under **Cloud Service**, select the cloud service that you created earlier.

Click **Publish**. It can take a few minutes to deploy the application and start the VMs.

Now when you run the chat application, the role instances communicate through Azure Service Bus, using a Service Bus topic. A topic is a message queue that allows multiple subscribers.

The backplane automatically creates the topic and the subscriptions. To see the subscriptions and message activity, open the Azure portal, select the Service Bus namespace, and click on "Topics".

It make take a few minutes for the message activity to show up in the dashboard.

SignalR manages the topic lifetime. As long as your application is deployed, don't try to manually delete topics or change settings on the topic.

Troubleshooting

System.InvalidOperationException "The only supported IsolationLevel is 'IsolationLevel.Serializable'."

This error can occur if the transaction level for an operation is set to something other than `Serializable`. Verify that no operations are being performed with other transaction levels.

SignalR Scaleout with Redis

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2.4

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

In this tutorial, you will use Redis to distribute messages across a SignalR application that is deployed on two separate IIS instances.

Redis is an in-memory key-value store. It also supports a messaging system with a publish/subscribe model. The SignalR Redis backplane uses the pub/sub feature to forward messages to other servers.

For this tutorial, you will use three servers:

- Two servers running Windows, which you will use to deploy a SignalR application.
- One server running Linux, which you will use to run Redis. For the screenshots in this tutorial, I used Ubuntu 12.04 TLS.

If you don't have three physical servers to use, you can create VMs on Hyper-V. Another option is to create VMs on Azure.

Although this tutorial uses the official Redis implementation, there is also a Windows port of Redis from MSOpenTech. Setup and configuration are different, but otherwise the steps are the same.

> **NOTE**
>
> SignalR scaleout with Redis does not support Redis clusters.

Overview

Before we get to the detailed tutorial, here is a quick overview of what you will do.

1. Install Redis and start the Redis server.
2. Add these NuGet packages to your application:
   - Microsoft.AspNet.SignalR
   - Microsoft.AspNet.SignalR.StackExchangeRedis
3. Create a SignalR application.
4. Add the following code to Startup.cs to configure the backplane:

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        // Any connection or hub wire up and configuration should go here
        GlobalHost.DependencyResolver.UseStackExchangeRedis("server", port, "password", "AppName");
        app.MapSignalR();
    }
}
```

Ubuntu on Hyper-V

Using Windows Hyper-V, you can easily create an Ubuntu VM on Windows Server.

Download the Ubuntu ISO from http://www.ubuntu.com.

In Hyper-V, add a new VM. In the **Connect Virtual Hard Disk** step, select **Create a virtual hard disk**.

In the **Installation Options** step, select **Image file (.iso)**, click **Browse**, and browse to the Ubuntu installation ISO.

Install Redis

Follow the steps at http://redis.io/download to download and build Redis.

```
wget http://redis.googlecode.com/files/redis-2.6.12.tar.gz
tar xzf redis-2.6.12.tar.gz
cd redis-2.6.12
make
```

This builds the Redis binaries in the `src` directory.

By default, Redis does not require a password. To set a password, edit the `redis.conf` file, which is located in the root directory of the source code. (Make a backup copy of the file before you edit it!) Add the following directive to `redis.conf`:

```
requirepass YourStrongPassword1234
```

Now start the Redis server:

```
src/redis-server redis.conf
```

Open port 6379, which is the default port that Redis listens on. (You can change the port number in the configuration file.)

Create the SignalR Application

Create a SignalR application by following either of these tutorials:

- Getting Started with SignalR 2.0
- Getting Started with SignalR 2.0 and MVC 5

Next, we'll modify the chat application to support scaleout with Redis. First, add the `Microsoft.AspNet.SignalR.StackExchangeRedis` NuGet package to your project. In Visual Studio, from the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.AspNet.SignalR.StackExchangeRedis
```

Next, open the Startup.cs file. Add the following code to the **Configuration** method:

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        // Any connection or hub wire up and configuration should go here
        GlobalHost.DependencyResolver.UseStackExchangeRedis("server", port, "password", "AppName");
        app.MapSignalR();
    }
}
```

- "server" is the name of the server that is running Redis.
- *port* is the port number
- "password" is the password that you defined in the redis.conf file.
- "AppName" is any string. SignalR creates a Redis pub/sub channel with this name.

For example:

```
GlobalHost.DependencyResolver.UseStackExchangeRedis("redis-server.cloudapp.net", 6379,
    "MyStrongPassword1234", "ChatApp");
```

Deploy and Run the Application

Prepare your Windows Server instances to deploy the SignalR application.

Add the IIS role. Include "Application Development" features, including the WebSocket Protocol.

Also include the Management Service (listed under "Management Tools").

Install Web Deploy 3.0. When you run IIS Manager, it will prompt you to install Microsoft Web Platform, or you can download the installer. In the Platform Installer, search for Web Deploy and install Web Deploy 3.0

Check that the Web Management Service is running. If not, start the service. (If you don't see Web Management Service in the list of Windows services, make sure that you installed the Management Service when you added the IIS role.)

By default, the Web Management Service listens on TCP port 8172. In Windows Firewall, create a new inbound rule to allow TCP traffic on port 8172. For more information, see Configuring Firewall Rules. (If you are hosting the VMs on Azure, you can do this directly in the Azure portal. See How to Set Up Endpoints to a Virtual Machine.)

Now you are ready to deploy the Visual Studio project from your development machine to the server. In Solution Explorer, right-click the solution and click **Publish**.

For more detailed documentation about web deployment, see Web Deployment Content Map for Visual Studio and ASP.NET.

If you deploy the application to two servers, you can open each instance in a separate browser window and see that they each receive SignalR messages from the other. (Of course, in a production environment, the two servers would sit behind a load balancer.)

If you're curious to see the messages that are sent to Redis, you can use the **redis-cli** client, which installs with Redis.

```
redis-cli -a password
SUBSCRIBE ChatApp
```

SignalR Scaleout with SQL Server

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

In this tutorial, you will use SQL Server to distribute messages across a SignalR application that is deployed in two separate IIS instances. You can also run this tutorial on a single test machine, but to get the full effect, you need to deploy the SignalR application to two or more servers. You must also install SQL Server on one of the servers, or on a separate dedicated server. Another option is to run the tutorial using VMs on Azure.

Prerequisites

Microsoft SQL Server 2005 or later. The backplane supports both desktop and server editions of SQL Server. It does not support SQL Server Compact Edition or Azure SQL Database. (If your application is hosted on Azure, consider the Service Bus backplane instead.)

Overview

Before we get to the detailed tutorial, here is a quick overview of what you will do.

1. Create a new empty database. The backplane will create the necessary tables in this database.
2. Add these NuGet packages to your application:
   - Microsoft.AspNet.SignalR
   - Microsoft.AspNet.SignalR.SqlServer
3. Create a SignalR application.
4. Add the following code to Startup.cs to configure the backplane:

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        // Any connection or hub wire up and configuration should go here
        string sqlConnectionString = "Connecton string to your SQL DB";
        GlobalHost.DependencyResolver.UseSqlServer(sqlConnectionString);
        app.MapSignalR();
    }
}
```

   This code configures the backplane with the default values for TableCount and MaxQueueLength. For information on changing these values, see SignalR Performance: Scaleout Metrics.

Configure the Database

Decide whether the application will use Windows authentication or SQL Server authentication to access the database. Regardless, make sure the database user has permissions to log in, create schemas, and create tables.

Create a new database for the backplane to use. You can give the database any name. You don't need to create any tables in the database; the backplane will create the necessary tables.

Enable Service Broker

It is recommended to enable Service Broker for the backplane database. Service Broker provides native support for messaging and queuing in SQL Server, which lets the backplane receive updates more efficiently. (However, the backplane also works without Service Broker.)

To check whether Service Broker is enabled, query the **is_broker_enabled** column in the **sys.databases** catalog view.

```
SELECT [name], [service_broker_guid], [is_broker_enabled]
FROM [master].[sys].[databases]
```

SQLQuery1.sql - MIK...QL\mikewasson (58))*

```
/****** Script for SelectTopNRows command from SSMS  ***
SELECT TOP 1000 [name]
      ,[service_broker_guid]
      ,[is_broker_enabled]
  FROM [master].[sys].[databases]
```

100 %

Results | Messages

	name	service_broker_guid	is_broker_enabled
1	master	00000000-0000-0000-0000-000000000000	0
2	tempdb	A86F7D5A-CD9E-439E-921F-281645FBCB92	1
3	model	00000000-0000-0000-0000-000000000000	0
4	msdb	F45AA830-122E-4297-8765-BC60F488E1C1	1
5	SignalR	DCBA980E-9228-4343-890F-41FA45CCB614	0

To enable Service Broker, use the following SQL query:

```
ALTER DATABASE YOUR_DATABASE SET ENABLE_BROKER
```

> **NOTE**
>
> If this query appears to deadlock, make sure there are no applications connected to the DB.

If you have enabled tracing, the traces will also show whether Service Broker is enabled.

Create a SignalR Application

Create a SignalR application by following either of these tutorials:

- Getting Started with SignalR 2.0
- Getting Started with SignalR 2.0 and MVC 5

Next, we'll modify the chat application to support scaleout with SQL Server. First, add the SignalR.SqlServer NuGet package to your project. In Visual Studio, from the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.AspNet.SignalR.SqlServer
```

Next, open the Startup.cs file. Add the following code to the **Configure** method:

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        // Any connection or hub wire up and configuration should go here
        string sqlConnectionString = "Connecton string to your SQL DB";
        GlobalHost.DependencyResolver.UseSqlServer(sqlConnectionString);
        app.MapSignalR();
    }
}
```

Deploy and Run the Application

Prepare your Windows Server instances to deploy the SignalR application.

Add the IIS role. Include "Application Development" features, including the WebSocket Protocol.

Also include the Management Service (listed under "Management Tools").

Install Web Deploy 3.0. When you run IIS Manager, it will prompt you to install Microsoft Web Platform, or you can download the installer. In the Platform Installer, search for Web Deploy and install Web Deploy 3.0

Check that the Web Management Service is running. If not, start the service. (If you don't see Web Management Service in the list of Windows services, make sure that you installed the Management Service when you added the IIS role.)

Finally, open port 8172 for TCP. This is the port that the Web Deploy tool uses.

Now you are ready to deploy the Visual Studio project from your development machine to the server. In Solution Explorer, right-click the solution and click **Publish**.

For more detailed documentation about web deployment, see Web Deployment Content Map for Visual Studio and ASP.NET.

If you deploy the application to two servers, you can open each instance in a separate browser window and see that they each receive SignalR messages from the other. (Of course, in a production environment, the two servers would sit behind a load balancer.)

After you run the application, you can see that SignalR has automatically created tables in the database:

SignalR manages the tables. As long as your application is deployed, don't delete rows, modify the table, and so forth.

SignalR Connection Density Testing with Crank

2/20/2020 • 3 minutes to read • Edit Online

by Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

> This article describes how to use the Crank tool to test an application with multiple simulated clients.

Once your application is running in its hosting environment (either an Azure web role, IIS, or self-hosted using Owin), you can test application's response to a high level of connection density using the Crank tool. The hosting environment can be an Internet Information Services (IIS) server, an Owin host, or an Azure web role. (Note: Performance counters are not available on Azure App Service Web Apps, so you will not be able to get performance data from a connection density test.)

Connection Density refers to the number of simultaneous TCP connections that can be established on a server. Each TCP connection incurs its own overhead, and opening a large number of idle connections will eventually create a memory bottleneck.

The SignalR codebase includes a load-testing tool called **Crank**. The latest version of Crank can be found in the Dev branch on GitHub. You can download a Zip archive of the Dev branch of the SignalR codebase here.

Crank may be used to fully saturate the server's memory in order to calculate the total number of idle connections possible on the server hardware. Alternatively, you may also use Crank to load test the server under a certain amount of memory pressure, by ramping up connections until a specific count or a specific memory threshold is reached.

When testing, it is important to use remote client(s) to avoid any competition for resources (i.e., TCP connections and memory). Monitor the client(s) to ensure that they are not hitting any bottlenecks that may prevent the server from reaching its full capacity (memory or CPU). You may need to increase the number of clients in order to fully load the server.

Running a Connection Density Test

This section describes the steps needed to run a connection density test on a SignalR application.

1. Download and build the Dev branch of the SignalR codebase. In a command prompt, navigate to <project directory>\src\Microsoft.AspNet.SignalR.Crank\bin\debug.
2. Deploy your application to its intended hosting environment. Make a note of the endpoint that your application uses; for example, in the application created in the Getting Started tutorial, the endpoint is `http://<yourhost>:8080/signalr`.
3. Install SignalR performance counters on the server. If your application is running on Azure, see Using SignalR Performance Counters in an Azure Web Role.

Once you've downloaded and built the codebase, and installed performance counters on your host, the Crank command-line tool can be found in the `src\Microsoft.AspNet.SignalR.Crank\bin\Debug` folder.

Available options for the Crank tool include:

- **/?**: Shows the help screen. The available options are also displayed if the **Url** parameter is omitted.

- **/Url**: The URL for SignalR connections. This parameter is required. For a SignalR application using the default mapping, the path will end in "/signalr".
- **/Transport**: The name of the transport used. The default is `auto`, which will select the best available protocol. Options include `WebSockets`, `ServerSentEvents`, and `LongPolling` (`ForeverFrame` is not an option for Crank, since the .NET client rather than Internet Explorer is used). For more information on how SignalR selects transports, see Transports and Fallbacks.
- **/BatchSize**: The number of clients added in each batch. The default is 50.
- **/ConnectInterval**: The interval in milliseconds between adding connections. The default is 500.
- **/Connections**: The number of connections used to load-test the application. The default is 100,000.
- **/ConnectTimeout**: The timeout in seconds before aborting the test. The default is 300.
- **MinServerMBytes**: The minimum server megabytes to reach. The default is 500.
- **SendBytes**: The size of the payload sent to the server in bytes. The default is 0.
- **SendInterval**: The delay in milliseconds between messages to the server. The default is 500.
- **SendTimeout**: The timeout in milliseconds for messages to the server. The default is 300.
- **ControllerUrl**: The Url where one client will host a controller hub. The default is null (no controller hub). The controller hub is started when the Crank session starts; no further contact between the controller hub and Crank is made.
- **NumClients**: The number of simulated clients to connect to the application. The default is one.
- **Logfile**: The filename for the logfile for the test run. The default is `crank.csv`.
- **SampleInterval**: The time in milliseconds between performance counter samples. The default is 1000.
- **SignalRInstance**: The instance name for the performance counters on the server. The default is to use the client connection state.

Example

The following command will test a site called `pfsignalr` on Azure that hosts an application on port 8080 with a hub named "ControllerHub", using 100 connections.

```
crank /Connections:100 /Url:http://pfsignalr.cloudapp.net:8080/signalr
```

Using SignalR performance counters in an Azure Web Role

9/16/2020 • 9 minutes to read • Edit Online

By Luke Latham

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

SignalR performance counters are used to monitor your app's performance in an Azure Web Role. The counters are captured by Microsoft Azure Diagnostics. You install SignalR performance counters on Azure with *signalr.exe*, the same tool used for standalone or on-premises apps. Since Azure roles are transient, you configure an app to install and register SignalR performance counters upon startup.

Prerequisites

- Visual Studio 2015 or 2017
- Microsoft Azure SDK for Visual Studio **Note: Restart your machine after installing the SDK.**
- Microsoft Azure subscription: To sign up for a free Azure trial account, see Azure Free Trial.

Creating an Azure Web Role application that exposes SignalR performance counters

1. Open Visual Studio.
2. In Visual Studio, select **File** > **New** > **Project**.
3. In the **New Project** dialog box, select the **Visual C#** > **Cloud** category on the left, and then select the **Azure Cloud Service** template. Name the app **SignalRPerfCounters** and select **OK**.

NOTE

If you don't see the **Cloud** template category or the **Azure Cloud Service** template, you need to install the **Azure development** workload for Visual Studio 2017. Choose the **Open Visual Studio Installer** link on the bottom-left side of the **New Project** dialog to open Visual Studio Installer. Select the **Azure development** workload, and then choose **Modify** to start installing the workload.

4. In the **New Microsoft Azure Cloud Service** dialog, select **ASP.NET Web Role** and select the > button to add the role to the project. Select **OK**.

5. In the **New ASP.NET Web Application - WebRole1** dialog, select the **MVC** template, and then select **OK**.

6. In **Solution Explorer**, open the *diagnostics.wadcfgx* file under **WebRole1**.

7. Replace the contents of the file with the following configuration and save the file:

```
<?xml version="1.0" encoding="utf-8"?>
<DiagnosticsConfiguration
xmlns="http://schemas.microsoft.com/ServiceHosting/2010/10/DiagnosticsConfiguration">
  <PublicConfig>
    <WadCfg>
      <DiagnosticMonitorConfiguration overallQuotaInMB="4096">
        <DiagnosticInfrastructureLogs scheduledTransferLogLevelFilter="Error" />
        <Logs scheduledTransferPeriod="PT1M" scheduledTransferLogLevelFilter="Error" />
        <Directories scheduledTransferPeriod="PT1M">
          <IISLogs containerName ="wad-iis-logfiles" />
          <FailedRequestLogs containerName ="wad-failedrequestlogs" />
        </Directories>
        <WindowsEventLog scheduledTransferPeriod="PT1M">
          <DataSource name="Application!*[System[(Level=1 or Level=2 or Level=3)]]" />
          <DataSource name="Windows Azure!*[System[(Level=1 or Level=2 or Level=3 or Level=4)]]" />
        </WindowsEventLog>
        <CrashDumps containerName="wad-crashdumps" dumpType="Mini">
          <CrashDumpConfiguration processName="WaIISHost.exe" />
          <CrashDumpConfiguration processName="WaWorkerHost.exe" />
          <CrashDumpConfiguration processName="w3wp.exe" />
        </CrashDumps>
        <PerformanceCounters scheduledTransferPeriod="PT1M">
```

```
          <PerformanceCounterConfiguration counterSpecifier="\Memory\Available MBytes"

          <PerformanceCounterConfiguration counterSpecifier="\SignalR(*)\Scaleout Send Queue Length"
sampleRate="PT10S" />
        </PerformanceCounters>
      </DiagnosticMonitorConfiguration>
    </WadCfg>
    <StorageAccount></StorageAccount>
  </PublicConfig>
  <PrivateConfig>
    <StorageAccount name="" key="" endpoint="" />
  </PrivateConfig>
  <IsEnabled>true</IsEnabled>
</DiagnosticsConfiguration>
```

8. Open the **Package Manager Console** from **Tools** > **NuGet Package Manager**. Enter the following commands to install the latest version of SignalR and the SignalR utilities package:

```
install-package microsoft.aspnet.signalr
install-package microsoft.aspnet.signalr.utils
```

9. Configure the app to install the SignalR performance counters into the role instance when it starts up or recycles. In **Solution Explorer**, right-click on the **WebRole1** project and select **Add** > **New Folder**. Name the new folder *Startup*.

10. Copy the *signalr.exe* file (added with the **Microsoft.AspNet.SignalR.Utils** package) from <project folder>/SignalRPerfCounters/packages/Microsoft.AspNet.SignalR.Utils.<version>/tools to the *Startup* folder you created in the previous step.

11. In **Solution Explorer**, right-click the *Startup* folder and select **Add** > **Existing Item**. In the dialog that appears, select *signalr.exe* and select **Add**.

12. Right-click on the *Startup* folder you created. Select **Add** > **New Item**. Select the **General** node, select **Text File**, and name the new item *SignalRPerfCounterInstall.cmd*. This command file will install the SignalR performance counters into the web role.

13. When Visual Studio creates the *SignalRPerfCounterInstall.cmd* file, it will automatically open in the main window. Replace the contents of the file with the following script, then save and close the file. This script executes *signalr.exe*, which adds the SignalR performance counters to the role instance.

```
SET SignalR_LogDir=%~dp0Log\
MKDIR "%SignalR_LogDir%"
cd %~dp0
signalr.exe ipc >> "%SignalR_LogDir%SignalR_Log.txt" 2>&1
net localgroup "Performance Monitor Users" "Network Service" /ADD >> "%SignalR_LogDir%NetworkAdd.txt"
2>&1
```

14. Select the *signalr.exe* file in **Solution Explorer**. In the file's **Properties**, set **Copy to Output Directory** to **Copy Always**.

15. Repeat the previous step for the *SignalRPerfCounterInstall.cmd* file.

16. Right-click on the *SignalRPerfCounterInstall.cmd* file and select **Open With**. In the dialog that appears, select **Binary Editor** and select **OK**.

17. In the binary editor, select any leading bytes in the file and delete them. Save and close the file.

18. Open *ServiceDefinition.csdef* and add a startup task that executes the *SignalrPerfCounterInstall.cmd* file when the service starts up:

```
<?xml version="1.0" encoding="utf-8"?>
<ServiceDefinition name="SignalRPerfCounters"
xmlns="http://schemas.microsoft.com/ServiceHosting/2008/10/ServiceDefinition" schemaVersion="2015-
04.2.6">
  <WebRole name="WebRole1" vmsize="Small">
    <Startup>
      <Task commandLine="Startup\SignalRPerfCounterInstall.cmd" executionContext="elevated"
taskType="background" />
    </Startup>
    <Sites>
      <Site name="Web">
        <Bindings>
          <Binding name="Endpoint1" endpointName="Endpoint1" />
        </Bindings>
      </Site>
    </Sites>
    <Endpoints>
      <InputEndpoint name="Endpoint1" protocol="http" port="80" />
    </Endpoints>
  </WebRole>
</ServiceDefinition>
```

19. Open `Views/Shared/_Layout.cshtml` and remove the jQuery bundle script from the end of the file.

```
<div class="container body-content">
    @RenderBody()
    <hr />
    <footer>
        <p>&copy; @DateTime.Now.Year - My ASP.NET Application</p>
    </footer>
</div>

@Scripts.Render("~/bundles/jquery")
@Scripts.Render("~/bundles/bootstrap")
@RenderSection("scripts", required: false)
</body>
</html>
```

20. Add a JavaScript client that continuously calls the `increment` method on the server. Open `Views/Home/Index.cshtml` and replace the contents with the following code:

```
@{
    ViewBag.Title = "Home Page";
}

<script src="~/Scripts/jquery-1.10.2.min.js"></script>
<script src="~/Scripts/jquery.signalR-2.2.1.min.js"></script>
<script src="~/signalr/hubs" type="text/javascript"></script>

<div id="body">
    <section class="featured">
        <div class="content-wrapper">
            <p>
                Hello World!
            </p>
            <div style="font-size:large;">
                My Counter: <span id="counter"></span>
            </div>
        </div>
    </section>
    <section class="content-wrapper main-content clear-fix"></section>
</div>

<script type="text/javascript">
  $(document).ready(function () {
    var hub = $.connection.myHub;

    hub.client.sendResult = function (x) {
      console.log('sendResult(' + x + ')');
      $("#counter").text(x);
      window.setTimeout(function () {
        hub.server.increment(x);
      }, 1000);
    };

    $.connection.hub.connected = function () {};
    $.connection.hub.disconnected = function () {};

    $.connection.hub.stateChanged(function (change) {
      console.log('new State' + change.newState);
      if (change.newState === $.signalR.connectionState.disconnected) {
        $.connection.hub.start();
      }
      if (change.newState === $.signalR.connectionState.reconnecting) {
        console.log('Re-connecting');
      } else if (change.newState === $.signalR.connectionState.connected) {
        console.log('The server is online');
      }
    });

    $.connection.hub.error(function (error) {
      console.log('error ' + error);
    });

    $.connection.hub.logging = true;

    $.connection.hub.reconnected(function () {
      console.log('Reconnected');
      hub.server.increment(0);
    });

    $.connection.hub.start().done(function () {
      console.log('hub started');
      hub.server.increment(0);
    });
  });
</script>
```

21. Create a new folder in the **WebRole1** project named *Hubs*. Right-click the *Hubs* folder in **Solution Explorer** and select **Add** > **New Item**. In the **Add New Item** dialog box, select the **Web** > **SignalR** category, and then select the **SignalR Hub Class (v2)** item template. Name the new hub *MyHub.cs* and select **Add**.

22. *MyHub.cs* will automatically open in the main window. Replace the contents with the following code, then save and close the file:

```
using System.Threading.Tasks;
using Microsoft.AspNet.SignalR;

namespace WebRole1.Hubs
{
    public class MyHub : Hub
    {
        public async Task Increment(int x)
        {
            await this.Clients.Caller.sendResult(x + 1);
        }
    }
}
```

23. *Crank.exe* is a connection density testing tool provided with the SignalR codebase. Since Crank requires a persistent connection, you add one to your site for use when testing. Add a new folder to the **WebRole1** project called *PersistentConnections*. Right-click this folder and select **Add** > **Class**. Name the new class file *MyPersistentConnections.cs* and select **Add**.

24. Visual Studio will open the *MyPersistentConnections.cs* file in the main window. Replace the contents with the following code, then save and close the file:

```
using System.Threading.Tasks;
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Infrastructure;

namespace WebRole1.PersistentConnections
{
    public class MyPersistentConnection : PersistentConnection
    {
        protected override Task OnReceived(IRequest request, string connectionId, string data)
        {
            //Return data to calling user
            return Connection.Send(connectionId, data);
        }
    }
}
```

25. Using the `Startup` class, the SignalR objects start when OWIN starts up. Open or create *Startup.cs* and replace the contents with the following code:

```
using Microsoft.Owin;
using Owin;
using WebRole1.PersistentConnections;

// Marks this class for automatic OWIN startup
[assembly: OwinStartup(typeof(WebRole1.Startup))]
namespace WebRole1
{
    public partial class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            ConfigureAuth(app);
            // Only needed if "No Authentication" was not selected for the project
            app.MapSignalR();
            app.MapSignalR<MyPersistentConnection>("/echo");
        }
    }
}
```

In the code above, the `OwinStartup` attribute marks this class to start OWIN. The `Configuration` method starts SignalR.

26. Test your application in the Microsoft Azure Emulator by pressing **F5**.

> **NOTE**
>
> If you encounter a **FileLoadException** at **MapSignalR**, change the binding redirects in *web.config* to the following:

```
<dependentAssembly>
  <assemblyIdentity name="Microsoft.Owin" publicKeyToken="31bf3856ad364e35" culture="neutral" />
  <bindingRedirect oldVersion="0.0.0.0-2.0.2.0" newVersion="2.0.0.0" />
</dependentAssembly>
<dependentAssembly>
  <assemblyIdentity name="Microsoft.Owin.Security" publicKeyToken="31bf3856ad364e35" culture="neutral"
/>
  <bindingRedirect oldVersion="0.0.0.0-2.0.2.0" newVersion="2.0.0.0" />
</dependentAssembly>
```

27. Wait about one minute. Open the Cloud Explorer tool window in Visual Studio (**View** > **Cloud Explorer**) and expand the path `(Local)/Storage Accounts/(Development)/Tables`. Double-click

WADPerformanceCountersTable. You should see SignalR counters in the table data. If you don't see the table, you may need to re-enter your Azure Storage credentials. You may need to select the **Refresh** button to see the table in **Cloud Explorer** or select the **Refresh** button in the open table window to see data in the table.

28. To test your application in the cloud, update the **ServiceConfiguration.Cloud.cscfg** file and set the `Microsoft.WindowsAzure.Plugins.Diagnostics.ConnectionString` to a valid Azure Storage account connection string.

```
<?xml version="1.0" encoding="utf-8"?>
<ServiceConfiguration serviceName="SignalRPerfCounters"
xmlns="http://schemas.microsoft.com/ServiceHosting/2008/10/ServiceConfiguration" osFamily="4"
osVersion="*" schemaVersion="2015-04.2.6">
  <Role name="WebRole1">
    <Instances count="1" />
    <ConfigurationSettings>
      <Setting name="Microsoft.WindowsAzure.Plugins.Diagnostics.ConnectionString"
value="DefaultEndpointsProtocol=https;AccountName=&lt;account-name&gt;;AccountKey=&lt;account-key&gt;"
/>
    </ConfigurationSettings>
  </Role>
</ServiceConfiguration>
```

29. Deploy the application to your Azure subscription. For details on how to deploy an application to Azure, see How to Create and Deploy a Cloud Service.

30. Wait a few minutes. In **Cloud Explorer**, locate the storage account you configured above and find the `WADPerformanceCountersTable` table in it. You should see SignalR counters in the table data. If you don't see the table, you may need to re-enter your Azure Storage credentials. You may need to select the **Refresh**

button to see the table in **Cloud Explorer** or select the **Refresh** button in the open table window to see data in the table.

Special thanks to Martin Richard for the original content used in this tutorial.

- Using SignalR with Web Apps in Azure App Service

Tutorial: SignalR Self-Host

9/16/2020 • 7 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This tutorial shows how to create a self-hosted SignalR 2 server, and how to connect to it with a JavaScript client.

Software versions used in the tutorial

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Using Visual Studio 2012 with this tutorial

To use Visual Studio 2012 with this tutorial, do the following:

- Update your Package Manager to the latest version.
- Install the Web Platform Installer.
- In the Web Platform Installer, search for and install **ASP.NET and Web Tools 2013.1 for Visual Studio 2012**. This will install Visual Studio templates for SignalR classes such as **Hub**.
- Some templates (such as **OWIN Startup Class**) will not be available; for these, use a Class file instead.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

A SignalR server is usually hosted in an ASP.NET application in IIS, but it can also be self-hosted (such as in a console application or Windows service) using the self-host library. This library, like all of SignalR 2, is built on OWIN (Open Web Interface for .NET). OWIN defines an abstraction between .NET web servers and web applications. OWIN decouples the web application from the server, which makes OWIN ideal for self-hosting a web application in your own process, outside of IIS.

Reasons for not hosting in IIS include:

- Environments where IIS is not available or desirable, such as an existing server farm without IIS.
- The performance overhead of IIS needs to be avoided.
- SignalR functionality is to be added to an existing application that runs in a Windows Service, Azure worker role, or other process.

If a solution is being developed as self-host for performance reasons, it's recommended to also test the

application hosted in IIS to determine the performance benefit.

This tutorial contains the following sections:

- Creating the server
- Accessing the server with a JavaScript client

Creating the server

In this tutorial, you'll create a server that's hosted in a console application, but the server can be hosted in any sort of process, such as a Windows service or Azure worker role. For sample code for hosting a SignalR server in a Windows Service, see Self-Hosting SignalR in a Windows Service.

1. Open Visual Studio 2013 with administrator privileges. Select **File**, **New Project**. Select **Windows** under the **Visual C#** node in the **Templates** pane, and select the **Console Application** template. Name the new project "SignalRSelfHost" and click **OK**.

2. Open the NuGet package manager console by selecting **Tools** > **NuGet Package Manager** > **Package Manager Console**.

3. In the package manager console, enter the following command:

```
Install-Package Microsoft.AspNet.SignalR.SelfHost
```

   This command adds the SignalR 2 Self-Host libraries to the project.

4. In the package manager console, enter the following command:

```
Install-Package Microsoft.Owin.Cors
```

   This command adds the Microsoft.Owin.Cors library to the project. This library will be used for cross-domain support, which is required for applications that host SignalR and a web page client in different domains. Since you'll be hosting the SignalR server and the web client on different ports, this means that cross-domain must be enabled for communication between these components.

5. Replace the contents of Program.cs with the following code.

```
using System;
using Microsoft.AspNet.SignalR;
using Microsoft.Owin.Hosting;
using Owin;
using Microsoft.Owin.Cors;

namespace SignalRSelfHost
{
    class Program
    {
        static void Main(string[] args)
        {
            // This will *ONLY* bind to localhost, if you want to bind to all addresses
            // use http://*:8080 to bind to all addresses.
            // See http://msdn.microsoft.com/library/system.net.httplistener.aspx
            // for more information.
            string url = "http://localhost:8080";
            using (WebApp.Start(url))
            {
                Console.WriteLine("Server running on {0}", url);
                Console.ReadLine();
            }
        }
    }
    class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            app.UseCors(CorsOptions.AllowAll);
            app.MapSignalR();
        }
    }
    public class MyHub : Hub
    {
        public void Send(string name, string message)
        {
            Clients.All.addMessage(name, message);
        }
    }
}
```

The above code includes three classes:

- **Program**, including the **Main** method defining the primary path of execution. In this method, a web application of type **Startup** is started at the specified URL (`http://localhost:8080`). If security is required on the endpoint, SSL can be implemented. See How to: Configure a Port with an SSL Certificate for more information.
- **Startup**, the class containing the configuration for the SignalR server (the only configuration this tutorial uses is the call to `UseCors`), and the call to `MapSignalR` , which creates routes for any Hub objects in the project.
- **MyHub**, the SignalR Hub class that the application will provide to clients. This class has a single method, **Send**, that clients will call to broadcast a message to all other connected clients.

6. Compile and run the application. The address that the server is running should show in a console window.

7. If execution fails with the exception `System.Reflection.TargetInvocationException was unhandled`, you will need to restart Visual Studio with administrator privileges.

8. Stop the application before proceeding to the next section.

Accessing the server with a JavaScript client

In this section, you'll use the same JavaScript client from the Getting Started tutorial. We'll only make one modification to the client, which is to explicitly define the hub URL. With a self-hosted application, the server may not necessarily be at the same address as the connection URL (due to reverse proxies and load balancers), so the URL needs to be defined explicitly.

1. In **Solution Explorer**, right-click on the solution and select **Add**, **New Project**. Select the **Web** node, and select the **ASP.NET Web Application** template. Name the project "JavascriptClient" and click **OK**.

2. Select the **Empty** template, and leave the remaining options unselected. Select **Create Project**.

3. In the package manager console, select the "JavascriptClient" project in the **Default project** drop-down, and execute the following command:

```
Install-Package Microsoft.AspNet.SignalR.JS
```

This command installs the SignalR and JQuery libraries that you'll need in the client.

4. Right-click on your project and select **Add**, **New Item**. Select the **Web** node, and select HTML Page. Name the page **Default.html**.

5. Replace the contents of the new HTML page with the following code. Verify that the script references here match the scripts in the Scripts folder of the project.

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR Simple Chat</title>
    <style type="text/css">
        .container {
            background-color: #99CCFF;
            border: thick solid #808080;
            padding: 20px;
            margin: 20px;
        }
    </style>
</head>
<body>
    <div class="container">
        <input type="text" id="message" />
        <input type="button" id="sendmessage" value="Send" />
        <input type="hidden" id="displayname" />
        <ul id="discussion"></ul>
    </div>
    <!--Script references. -->
    <!--Reference the jQuery library. -->
    <script src="Scripts/jquery-1.6.4.min.js"></script>
    <!--Reference the SignalR library. -->
    <script src="Scripts/jquery.signalR-2.1.0.min.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="http://localhost:8080/signalr/hubs"></script>
    <!--Add script to update the page and send messages.-->
    <script type="text/javascript">
        $(function () {
        //Set the hubs URL for the connection
            $.connection.hub.url = "http://localhost:8080/signalr";

            // Declare a proxy to reference the hub.
            var chat = $.connection.myHub;

            // Create a function that the hub can call to broadcast messages.
            chat.client.addMessage = function (name, message) {
                // Html encode display name and message.
                var encodedName = $('<div />').text(name).html();
                var encodedMsg = $('<div />').text(message).html();
                // Add the message to the page.
                $('#discussion').append('<li><strong>' + encodedName
                    + '</strong>:  ' + encodedMsg + '</li>');
            };
            // Get the user name and store it to prepend to messages.
            $('#displayname').val(prompt('Enter your name:', ''));
            // Set initial focus to message input box.
            $('#message').focus();
            // Start the connection.
            $.connection.hub.start().done(function () {
                $('#sendmessage').click(function () {
                    // Call the Send method on the hub.
                    chat.server.send($('#displayname').val(), $('#message').val());
                    // Clear text box and reset focus for next comment.
                    $('#message').val('').focus();
                });
            });
        });
    </script>
</body>
</html>
```

The following code (highlighted in the code sample above) is the addition that you've made to the client used in the Getting Stared tutorial (in addition to upgrading the code to SignalR version 2 beta). This line of code explicitly sets the base connection URL for SignalR on the server.

```
//Set the hubs URL for the connection
$.connection.hub.url = "http://localhost:8080/signalr";
```

6. Right-click on the solution, and select **Set Startup Projects...**. Select the **Multiple startup projects** radio button, and set both projects' **Action** to **Start**.

7. Right-click on "Default.html" and select **Set As Start Page**.

8. Run the application. The server and page will launch. You may need to reload the web page (or select **Continue** in the debugger) if the page loads before the server is started.

9. In the browser, provide a username when prompted. Copy the page's URL into another browser tab or window and provide a different username. You will be able to send messages from one browser pane to the other, as in the Getting Started tutorial.

Using SignalR with Web Apps in Azure App Service

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document describes how to configure a SignalR application that runs on Microsoft Azure.

Software versions used in the tutorial

- Visual Studio 2013 or Visual Studio 2012
- .NET 4.5
- SignalR version 2
- Azure SDK 2.3 for Visual Studio 2013 or 2012

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum, StackOverflow.com, or the Microsoft Azure forums.

Table of Contents

- Introduction
- Deploying a SignalR Web App to Azure App Service
- Enabling WebSockets on Azure App Service
- Using the Azure Redis Cache Backplane
- Next Steps

Introduction

ASP.NET SignalR can be used to bring a new level of interactivity between servers and web or .NET clients. When hosted in Azure, SignalR applications can take advantage of the highly available, scalable, and performant environment that running in the cloud provides.

Deploying a SignalR Web App to Azure App Service

SignalR doesn't add any particular complications to deploying an application to Azure versus deploying to an on-premises server. An application that uses SignalR can be hosted in Azure without any changes in configuration or other settings (though for WebSockets support, see Enabling WebSockets on Azure App Service below.) For this tutorial, you'll deploy the application created in the Getting Started Tutorial to Azure.

Prerequisites

- Visual Studio 2013. If you don't have Visual Studio, Visual Studio 2013 Express for Web is included in the install of the Azure SDK.

- Azure SDK 2.3 for Visual Studio 2013 or Azure SDK 2.3 for Visual Studio 2012.
- To complete this tutorial, you will need an Azure subscription. You can activate your MSDN subscriber benefits, or sign up for a trial subscription.

Deploying a SignalR web app to Azure

1. Complete the Getting Started Tutorial, or download the finished project from Code Gallery.
2. In Visual Studio, select **Build**, **Publish SignalR Chat**.
3. In the "Publish Web" dialog, select "Windows Azure Web Sites".

4. If you aren't signed in to your Microsoft account, click **Sign In...** in the "Select Existing Web Site" dialog, and sign in.

5. In the "Select Existing Web Site" dialog, click **New**.

6. In the "Create site on Windows Azure" dialog, enter a unique app name. Select the region closest to you in the Region dropdown. Click **Create**.

7. In the "Publish Web" dialog, click **Publish**.

8. When the app has completed publishing, the SignalR Chat application hosted in Azure App Service Web Apps will open in a browser.

Enabling WebSockets on Azure App Service Web Apps

WebSockets needs to be explicitly enabled in your web app to be used in a SignalR application; otherwise, other protocols will be used (See Transports and Fallbacks for details).

In order to use WebSockets on Azure App Service Web Apps, enable it in the configuration section of the web app. To do this, open your web app in the Azure Management Portal, and select Configure.

At the top of the configuration page, ensure that .NET 4.5 is used for your web app.

On the configuration page, in the **WebSockets** setting, select **On**.

At the bottom of the Configuration page, select **Save** to save your changes.

Using the Azure Redis Cache Backplane

If you use multiple instances for your web app, and the users of those instances need to interact with one another (so that, for instance, chat messages created in one instance can reach the users connected to other instances), the Azure Redis Cache backplane must be implemented in your application.

Next Steps

For more information on Web Apps in Azure App Service, see Web Apps overview.

- Dependency Injection in SignalR

Dependency Injection in SignalR

2/20/2020 • 8 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Dependency injection is a way to remove hard-coded dependencies between objects, making it easier to replace an object's dependencies, either for testing (using mock objects) or to change run-time behavior. This tutorial shows how to perform dependency injection on SignalR hubs. It also shows how to use IoC containers with SignalR. An IoC container is a general framework for dependency injection.

What is Dependency Injection?

Skip this section if you are already familiar with dependency injection.

Dependency injection (DI) is a pattern where objects are not responsible for creating their own dependencies. Here is a simple example to motivate DI. Suppose you have an object that needs to log messages. You might define a logging interface:

```
interface ILogger
{
    void LogMessage(string message);
}
```

In your object, you can create an `ILogger` to log messages:

```
// Without dependency injection.
class SomeComponent
{
    ILogger _logger = new FileLogger(@"C:\logs\log.txt");

    public void DoSomething()
    {
        _logger.LogMessage("DoSomething");
    }
}
```

This works, but it's not the best design. If you want to replace `FileLogger` with another `ILogger` implementation, you will have to modify `SomeComponent`. Supposing that a lot of other objects use `FileLogger`, you will need to change all of them. Or if you decide to make `FileLogger` a singleton, you'll also need to make changes throughout the application.

A better approach is to "inject" an `ILogger` into the object—for example, by using a constructor argument:

```
// With dependency injection.
class SomeComponent
{
    ILogger _logger;

    // Inject ILogger into the object.
    public SomeComponent(ILogger logger)
    {
        if (logger == null)
        {
            throw new NullReferenceException("logger");
        }
        _logger = logger;
    }

    public void DoSomething()
    {
        _logger.LogMessage("DoSomething");
    }
}
```

Now the object is not responsible for selecting which `ILogger` to use. You can switch `ILogger` implementations without changing the objects that depend on it.

```
var logger = new TraceLogger(@"C:\logs\log.etl");
var someComponent = new SomeComponent(logger);
```

This pattern is called constructor injection. Another pattern is setter injection, where you set the dependency through a setter method or property.

Simple Dependency Injection in SignalR

Consider the Chat application from the tutorial Getting Started with SignalR. Here is the hub class from that application:

```
public class ChatHub : Hub
{
    public void Send(string name, string message)
    {
        Clients.All.addMessage(name, message);
    }
}
```

Suppose that you want to store chat messages on the server before sending them. You might define an interface that abstracts this functionality, and use DI to inject the interface into the `ChatHub` class.

```
public interface IChatRepository
{
    void Add(string name, string message);
    // Other methods not shown.
}

public class ChatHub : Hub
{
    private IChatRepository _repository;

    public ChatHub(IChatRepository repository)
    {
        _repository = repository;
    }

    public void Send(string name, string message)
    {
        _repository.Add(name, message);
        Clients.All.addMessage(name, message);
    }
```

The only problem is that a SignalR application does not directly create hubs; SignalR creates them for you. By default, SignalR expects a hub class to have a parameterless constructor. However, you can easily register a function to create hub instances, and use this function to perform DI. Register the function by calling **GlobalHost.DependencyResolver.Register**.

```
public void Configuration(IAppBuilder app)
{
    GlobalHost.DependencyResolver.Register(
        typeof(ChatHub),
        () => new ChatHub(new ChatMessageRepository()));

    App.MapSignalR();

    // ...
}
```

Now SignalR will invoke this anonymous function whenever it needs to create a `ChatHub` instance.

IoC Containers

The previous code is fine for simple cases. But you still had to write this:

```
... new ChatHub(new ChatMessageRepository()) ...
```

In a complex application with many dependencies, you might need to write a lot of this "wiring" code. This code can be hard to maintain, especially if dependencies are nested. It is also hard to unit test.

One solution is to use an IoC container. An IoC container is a software component that is responsible for managing dependencies.You register types with the container, and then use the container to create objects. The container automatically figures out the dependency relations. Many IoC containers also allow you to control things like object lifetime and scope.

> **NOTE**
> "IoC" stands for "inversion of control", which is a general pattern where a framework calls into application code. An IoC container constructs your objects for you, which "inverts" the usual flow of control.

Using IoC Containers in SignalR

The Chat application is probably too simple to benefit from an IoC container. Instead, let's look at the StockTicker sample.

The StockTicker sample defines two main classes:

- `StockTickerHub`: The hub class, which manages client connections.
- `StockTicker`: A singleton that holds stock prices and periodically updates them.

`StockTickerHub` holds a reference to the `StockTicker` singleton, while `StockTicker` holds a reference to the **IHubConnectionContext** for the `StockTickerHub`. It uses this interface to communicate with `StockTickerHub` instances. (For more information, see Server Broadcast with ASP.NET SignalR.)

We can use an IoC container to untangle these dependencies a bit. First, let's simplify the `StockTickerHub` and `StockTicker` classes. In the following code, I've commented out the parts that we don't need.

Remove the parameterless constructor from `StockTickerHub`. Instead, we will always use DI to create the hub.

```
[HubName("stockTicker")]
public class StockTickerHub : Hub
{
    private readonly StockTicker _stockTicker;

    //public StockTickerHub() : this(StockTicker.Instance) { }

    public StockTickerHub(StockTicker stockTicker)
    {
        if (stockTicker == null)
        {
            throw new ArgumentNullException("stockTicker");
        }
        _stockTicker = stockTicker;
    }

    // ...
```

For StockTicker, remove the singleton instance. Later, we'll use the IoC container to control the StockTicker lifetime. Also, make the constructor public.

```
public class StockTicker
{
    //private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(
    //    () => new StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));

    // Important! Make this constructor public.
    public StockTicker(IHubConnectionContext<dynamic> clients)
    {
        if (clients == null)
        {
            throw new ArgumentNullException("clients");
        }

        Clients = clients;
        LoadDefaultStocks();
    }

    //public static StockTicker Instance
    //{
    //    get
    //    {
    //        return _instance.Value;
    //    }
    //}
```

Next, we can refactor the code by creating an interface for `StockTicker`. We'll use this interface to decouple the `StockTickerHub` from the `StockTicker` class.

Visual Studio makes this kind of refactoring easy. Open the file StockTicker.cs, right-click on the `StockTicker` class declaration, and select **Refactor** ... **Extract Interface**.

In the **Extract Interface** dialog, click **Select All**. Leave the other defaults. Click **OK**.

Visual Studio creates a new interface named `IStockTicker`, and also changes `StockTicker` to derive from `IStockTicker`.

Open the file IStockTicker.cs and change the interface to **public**.

```
public interface IStockTicker
{
    void CloseMarket();
    IEnumerable<Stock> GetAllStocks();
    MarketState MarketState { get; }
    void OpenMarket();
    void Reset();
}
```

In the `StockTickerHub` class, change the two instances of `StockTicker` to `IStockTicker`:

```
[HubName("stockTicker")]
public class StockTickerHub : Hub
{
    private readonly IStockTicker _stockTicker;

    public StockTickerHub(IStockTicker stockTicker)
    {
        if (stockTicker == null)
        {
            throw new ArgumentNullException("stockTicker");
        }
        _stockTicker = stockTicker;
    }
```

Creating an `IStockTicker` interface isn't strictly necessary, but I wanted to show how DI can help to reduce coupling between components in your application.

Add the Ninject Library

There are many open-source IoC containers for .NET. For this tutorial, I'll use Ninject. (Other popular libraries include Castle Windsor, Spring.Net, Autofac, Unity, and StructureMap.)

Use NuGet Package Manager to install the Ninject library. In Visual Studio, from the **Tools** menu select **NuGet Package Manager** > **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Ninject -Version 3.0.1.10
```

Replace the SignalR Dependency Resolver

To use Ninject within SignalR, create a class that derives from **DefaultDependencyResolver**.

```
internal class NinjectSignalRDependencyResolver : DefaultDependencyResolver
{
    private readonly IKernel _kernel;
    public NinjectSignalRDependencyResolver(IKernel kernel)
    {
        _kernel = kernel;
    }

    public override object GetService(Type serviceType)
    {
        return _kernel.TryGet(serviceType) ?? base.GetService(serviceType);
    }

    public override IEnumerable<object> GetServices(Type serviceType)
    {
        return _kernel.GetAll(serviceType).Concat(base.GetServices(serviceType));
    }
}
```

This class overrides the **GetService** and **GetServices** methods of **DefaultDependencyResolver**. SignalR calls these methods to create various objects at runtime, including hub instances, as well as various services used internally by SignalR.

- The **GetService** method creates a single instance of a type. Override this method to call the Ninject kernel's **TryGet** method. If that method returns null, fall back to the default resolver.
- The **GetServices** method creates a collection of objects of a specified type. Override this method to concatenate the results from Ninject with the results from the default resolver.

Configure Ninject Bindings

Now we'll use Ninject to declare type bindings.

Open your application's Startup.cs class (that you either created manually as per the package instructions in `readme.txt`, or that was created by adding authentication to your project). In the `Startup.Configuration` method, create the Ninject container, which Ninject calls the *kernel*.

```
var kernel = new StandardKernel();
```

Create an instance of our custom dependency resolver:

```
var resolver = new NinjectSignalRDependencyResolver(kernel);
```

Create a binding for `IStockTicker` as follows:

```
kernel.Bind<IStockTicker>()
    .To<Microsoft.AspNet.SignalR.StockTicker.StockTicker>()  // Bind to StockTicker.
    .InSingletonScope();  // Make it a singleton object.
```

This code is saying two things. First, whenever the application needs an `IStockTicker`, the kernel should create an instance of `StockTicker`. Second, the `StockTicker` class should be a created as a singleton object. Ninject will create one instance of the object, and return the same instance for each request.

Create a binding for **IHubConnectionContext** as follows:

```
kernel.Bind(typeof(IHubConnectionContext<dynamic>)).ToMethod(context =>
                    resolver.Resolve<IConnectionManager>().GetHubContext<StockTickerHub>().Clients
                     ).WhenInjectedInto<IStockTicker>();
```

This code creates an anonymous function that returns an **IHubConnection**. The **WhenInjectedInto** method tells Ninject to use this function only when creating `IStockTicker` instances. The reason is that SignalR creates **IHubConnectionContext** instances internally, and we don't want to override how SignalR creates them. This function only applies to our `StockTicker` class.

Pass the dependency resolver into the **MapSignalR** method by adding a hub configuration:

```
var config = new HubConfiguration();
config.Resolver = resolver;
Microsoft.AspNet.SignalR.StockTicker.Startup.ConfigureSignalR(app, config);
```

Update the Startup.ConfigureSignalR method in the sample's Startup class with the new parameter:

```
public static void ConfigureSignalR(IAppBuilder app, HubConfiguration config)
{
    app.MapSignalR(config);
}
```

Now SignalR will use the resolver specified in **MapSignalR**, instead of the default resolver.

Here is the complete code listing for `Startup.Configuration`.

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        // For more information on how to configure your application, visit https://go.microsoft.com/fwlink/?
LinkID=316888

        var kernel = new StandardKernel();
        var resolver = new NinjectSignalRDependencyResolver(kernel);

        kernel.Bind<IStockTicker>()
            .To<Microsoft.AspNet.SignalR.StockTicker.StockTicker>()  // Bind to StockTicker.
            .InSingletonScope();  // Make it a singleton object.

        kernel.Bind(typeof(IHubConnectionContext<dynamic>)).ToMethod(context =>
                resolver.Resolve<IConnectionManager>().GetHubContext<StockTickerHub>().Clients
                    ).WhenInjectedInto<IStockTicker>();

        var config = new HubConfiguration();
        config.Resolver = resolver;
        Microsoft.AspNet.SignalR.StockTicker.Startup.ConfigureSignalR(app, config);
    }
}
```

To run the StockTicker application in Visual Studio, press F5. In the browser window, navigate to `http://localhost:*port*/SignalR.Sample/StockTicker.html`.

The application has exactly the same functionality as before. (For a description, see Server Broadcast with ASP.NET SignalR.) We haven't changed the behavior; just made the code easier to test, maintain, and evolve.

SignalR Releases

2/20/2020 • 2 minutes to read • Edit Online

Information about SignalR releases and how to upgrade from earlier to later releases.

- Upgrading SignalR 1.x Projects to version 2

Upgrading SignalR 1.x Projects to version 2

2/20/2020 • 3 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to upgrade an existing SignalR 1.x project to SignalR 2.x, and how to troubleshoot issues that may arise during the upgrade process.

Software versions used in the tutorial

- Visual Studio 2013
- .NET 4.5
- SignalR versions 1 and 2

Using Visual Studio 2012 with this tutorial

To use Visual Studio 2012 with this tutorial, do the following:

- Update your Package Manager to the latest version.
- Install the Web Platform Installer.
- In the Web Platform Installer, search for and install **ASP.NET and Web Tools 2013.1 for Visual Studio 2012**. This will install Visual Studio templates for SignalR classes such as **Hub**.
- Some templates (such as **OWIN Startup Class**) will not be available; for these, use a Class file instead.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

SignalR 2 offers a consistent development experience across server platforms using OWIN. This article describes the few steps that are needed to update a SignalR 1.x application to version 2.

While it is encouraged to upgrade applications to SignalR 2, SignalR 1.x will still be supported.

This tutorial describes how to upgrade a web-hosted application to SignalR 2. Self-hosted applications (those that host a server in a console application, Windows service, or other process) are now supported under SignalR 2. For information on how to get started creating a self-hosted application with SignalR 2, see Tutorial: SignalR Self-Host.

Contents

The following sections describe tasks involved with upgrading SignalR projects, and how to troubleshoot issues that may arise.

- Example: Upgrading the Getting Started tutorial to SignalR 2
- Troubleshooting errors encountered during upgrading

Example: Upgrading the Getting Started tutorial application to SignalR 2

In this section, you'll update the application created in the SignalR 1.x version of the Getting Started Tutorial to use SignalR 2.

1. Once you've finished the Getting Started tutorial, right-click on the project, and select **Properties**. Verify that the **Target framework** is set to **.NET Framework 4.5.**

2. Open the Package Manager Console. Remove SignalR 1.x from the project using the following command:

```
Uninstall-Package Microsoft.AspNet.SignalR -RemoveDependencies
```

3. Install SignalR 2 using the following command:

```
Install-Package Microsoft.AspNet.SignalR
```

4. In the HTML page, update the script reference for SignalR to match the version of the script now included in the project.

```
<!--Reference the SignalR library. -->
<script src="Scripts/jquery.signalR-2.1.0.min.js"></script>
```

5. In the global application class, remove the call to MapHubs.

```
protected void Application_Start(object sender, EventArgs e)
{
    RouteTable.Routes.MapHubs();
}
```

6. Right-click the solution, and select **Add**, **New Item...**. In the dialog, select **Owin Startup Class**. Name the new class **Startup.cs**.

7. Replace the contents of Startup.cs with the following code:

```
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(SignalRChat.Startup))]
namespace SignalRChat
{

    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            app.MapSignalR();
        }
    }
}
```

The assembly attribute adds the class to Owin's startup process, which executes the `Configuration` method when Owin starts up. This in turn calls the `MapSignalR` method, which creates routes for all SignalR hubs in the application.

8. Run the project, and copy the URL of the main page into another browser or browser pane, as before. Each page will ask for a username, and messages sent from each page should be visible in both browser panes.

Troubleshooting errors encountered during upgrading

This section describes issues that may arise during upgrading. For a more comprehensive list of errors and issues that may occur with a SignalR application, see SignalR Troubleshooting.

'The call is ambiguous between the following methods or properties'

This error will occur if a reference to `Microsoft.AspNet.SignalR.Owin` is not removed. This package is deprecated; the reference must be removed and the 1.x version of the SelfHost package must be uninstalled.

Hub methods fail silently

Verify that the script references in your client are up to date, and that the `OwinStartup` attribute for your Startup class has the correct class and assembly names for your project. Also, try opening up the hubs address (/signalr/hubs) in your browser; any error that appears will offer more information about what's going wrong.

SignalR Older Versions

Tutorial: Getting Started with SignalR 1.x

2/20/2020 • 8 minutes to read • Edit Online

by Patrick Fletcher, Tim Teebken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This tutorial shows how to use SignalR to create a real-time chat application. You will add SignalR to an empty ASP.NET web application and create an HTML page to send and display messages.

Overview

This tutorial introduces SignalR development by showing how to build a simple browser-based chat application. You will add the SignalR library to an empty ASP.NET web application, create a hub class for sending messages to clients, and create an HTML page that lets users send and receive chat messages. For a similar tutorial that shows how to create a chat application in MVC 4 using an MVC view, see Getting Started with SignalR and MVC 4.

NOTE

This tutorial uses the release (1.x) version of SignalR. For details on changes between SignalR 1.x and 2.0, see Upgrading SignalR 1.x Projects.

SignalR is an open-source .NET library for building web applications that require live user interaction or real-time data updates. Examples include social applications, multiuser games, business collaboration, and news, weather, or financial update applications. These are often called real-time applications.

SignalR simplifies the process of building real-time applications. It includes an ASP.NET server library and a JavaScript client library to make it easier to manage client-server connections and push content updates to clients. You can add the SignalR library to an existing ASP.NET application to gain real-time functionality.

The tutorial demonstrates the following SignalR development tasks:

- Adding the SignalR library to an ASP.NET web application.
- Creating a hub class to push content to clients.
- Using the SignalR jQuery library in a web page to send messages and display updates from the hub.

The following screen shot shows the chat application running in a browser. Each new user can post comments and see comments added after the user joins the chat.

Sections:

- Set up the Project
- Run the Sample
- Examine the Code
- Next Steps

Set up the Project

This section shows how to create an empty ASP.NET web application, add SignalR, and create the chat application.

Prerequisites:

- Visual Studio 2010 SP1 or 2012. If you do not have Visual Studio, see ASP.NET Downloads to get the free Visual Studio 2012 Express Development Tool.
- Microsoft ASP.NET and Web Tools 2012.2. For Visual Studio 2012, this installer adds new ASP.NET features including SignalR templates to Visual Studio. For Visual Studio 2010 SP1, an installer is not available but you can complete the tutorial by installing the SignalR NuGet package as described in the setup steps.

The following steps use Visual Studio 2012 to create an ASP.NET Empty Web Application and add the SignalR library:

1. In Visual Studio create an ASP.NET Empty Web Application.

2. Open the **Package Manager Console** by selecting **Tools | NuGet Package Manager | Package Manager Console**. Enter the following command into the console window:

```
Install-Package Microsoft.AspNet.SignalR -Version 1.1.3
```

   This command installs the latest version of SignalR 1.x.

3. In **Solution Explorer**, right-click the project, select **Add | Class**. Name the new class **ChatHub**.

4. In **Solution Explorer** expand the Scripts node. Script libraries for jQuery and SignalR are visible in the project.

5. Replace the code in the **ChatHub** class with the following code.

```
using System;
using System.Web;
using Microsoft.AspNet.SignalR;
namespace SignalRChat
{
    public class ChatHub : Hub
    {
        public void Send(string name, string message)
        {
            // Call the broadcastMessage method to update clients.
            Clients.All.broadcastMessage(name, message);
        }
    }
}
```

6. In **Solution Explorer**, right-click the project, then click **Add | New Item**. In the **Add New Item** dialog, select **Global Application Class** and click **Add**.

7. Add the following `using` statements after the provided `using` statements in the Global.asax.cs class.

```
using System.Web.Routing;
using Microsoft.AspNet.SignalR;
```

8. Add the following line of code in the `Application_Start` method of the Global class to register the default route for SignalR hubs.

```
// Register the default hubs route: ~/signalr/hubs
RouteTable.Routes.MapHubs();
```

9. In **Solution Explorer**, right-click the project, then click **Add | New Item**. In the **Add New Item** dialog, select Html Page and click **Add**.

10. In **Solution Explorer**, right-click the HTML page you just created and click **Set as Start Page**.

11. Replace the default code in the HTML page with the following code.

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR Simple Chat</title>
    <style type="text/css">
        .container {
            background-color: #99CCFF;
            border: thick solid #808080;
            padding: 20px;
            margin: 20px;
        }
    </style>
</head>
<body>
    <div class="container">
        <input type="text" id="message" />
        <input type="button" id="sendmessage" value="Send" />
        <input type="hidden" id="displayname" />
        <ul id="discussion">
        </ul>
    </div>
    <!--Script references. -->
    <!--Reference the jQuery library. -->
    <script src="/Scripts/jquery-1.6.4.min.js" ></script>
    <!--Reference the SignalR library. -->
    <script src="/Scripts/jquery.signalR-1.1.4.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="/signalr/hubs"></script>
    <!--Add script to update the page and send messages.-->
    <script type="text/javascript">
        $(function () {
            // Declare a proxy to reference the hub.
            var chat = $.connection.chatHub;
            // Create a function that the hub can call to broadcast messages.
            chat.client.broadcastMessage = function (name, message) {
                // Html encode display name and message.
                var encodedName = $('<div />').text(name).html();
                var encodedMsg = $('<div />').text(message).html();
                // Add the message to the page.
                $('#discussion').append('<li><strong>' + encodedName
                    + '</strong>:  ' + encodedMsg + '</li>');
            };
            // Get the user name and store it to prepend to messages.
            $('#displayname').val(prompt('Enter your name:', ''));
            // Set initial focus to message input box.
            $('#message').focus();
            // Start the connection.
            $.connection.hub.start().done(function () {
                $('#sendmessage').click(function () {
                    // Call the Send method on the hub.
                    chat.server.send($('#displayname').val(), $('#message').val());
                    // Clear text box and reset focus for next comment.
                    $('#message').val('').focus();
                });
            });
        });
    </script>
</body>
</html>
```

12. **Save All** for the project.

Run the Sample

1. Press F5 to run the project in debug mode. The HTML page loads in a browser instance and prompts for a

user name.

2. Enter a user name.

3. Copy the URL from the address line of the browser and use it to open two more browser instances. In each browser instance, enter a unique user name.

4. In each browser instance, add a comment and click **Send**. The comments should display in all browser instances.

> **NOTE**
>
> This simple chat application does not maintain the discussion context on the server. The hub broadcasts comments to all current users. Users who join the chat later will see messages added from the time they join.

The following screen shot shows the chat application running in three browser instances, all of which are updated when one instance sends a message:

5. In **Solution Explorer**, inspect the **Script Documents** node for the running application. There is a script file named **hubs** that the SignalR library dynamically generates at runtime. This file manages the communication between jQuery script and server-side code.

Examine the Code

The SignalR chat application demonstrates two basic SignalR development tasks: creating a hub as the main coordination object on the server, and using the SignalR jQuery library to send and receive messages.

SignalR Hubs

In the code sample the **ChatHub** class derives from the **Microsoft.AspNet.SignalR.Hub** class. Deriving from the **Hub** class is a useful way to build a SignalR application. You can create public methods on your hub class and then access those methods by calling them from jQuery scripts in a web page.

In the chat code, clients call the **ChatHub.Send** method to send a new message. The hub in turn sends the message to all clients by calling **Clients.All.broadcastMessage**.

The **Send** method demonstrates several hub concepts :

- Declare public methods on a hub so that clients can call them.
- Use the **Microsoft.AspNet.SignalR.Hub.Clients** dynamic property to access all clients connected to this hub.
- Call a jQuery function on the client (such as the `broadcastMessage` function) to update clients.

```
public class ChatHub : Hub
{
    public void Send(string name, string message)
    {
        // Call the broadcastMessage method to update clients.
        Clients.All.broadcastMessage(name, message);
    }
}
```

SignalR and jQuery

The HTML page in the code sample shows how to use the SignalR jQuery library to communicate with a SignalR hub. The essential tasks in the code are declaring a proxy to reference the hub, declaring a function that the server can call to push content to clients, and starting a connection to send messages to the hub.

The following code declares a proxy for a hub.

```
var chat = $.connection.chatHub;
```

> **NOTE**
> In jQuery the reference to the server class and its members is in camel case. The code sample references the C# **ChatHub** class in jQuery as **chatHub**.

The following code is how you create a callback function in the script. The hub class on the server calls this function to push content updates to each client. The two lines that HTML encode the content before displaying it are optional and show a simple way to prevent script injection.

```
chat.client.broadcastMessage = function (name, message) {
        // Html encode display name and message.
        var encodedName = $('<div />').text(name).html();
        var encodedMsg = $('<div />').text(message).html();
        // Add the message to the page.
        $('#discussion').append('<li><strong>' + encodedName
            + '</strong>:  ' + encodedMsg + '</li>');
    };
```

The following code shows how to open a connection with the hub. The code starts the connection and then passes it a function to handle the click event on the **Send** button in the HTML page.

> **NOTE**
> This approach insures that the connection is established before the event handler executes.

```
$.connection.hub.start().done(function () {
        $('#sendmessage').click(function () {
            // Call the Send method on the hub.
            chat.server.send($('#displayname').val(), $('#message').val());
            // Clear text box and reset focus for next comment.
            $('#message').val('').focus();
        });
    });
```

Next Steps

You learned that SignalR is a framework for building real-time web applications. You also learned several SignalR development tasks: how to add SignalR to an ASP.NET application, how to create a hub class, and how to send and receive messages from the hub.

You can make the sample application in this tutorial or other SignalR applications available over the Internet by deploying them to a hosting provider. Microsoft offers free web hosting for up to 10 web sites in a free Windows Azure trial account. For a walkthrough on how to deploy the sample SignalR application, see Publish the SignalR Getting Started Sample as a Windows Azure Web Site. For detailed information about how to deploy a Visual Studio web project to a Windows Azure Web Site, see Deploying an ASP.NET Application to a Windows Azure Web Site. (Note: The WebSocket transport is not currently supported for Windows Azure Web Sites. When WebSocket transport is not available, SignalR uses the other available transports as described in the Transports section of the Introduction to SignalR topic.)

To learn more advanced SignalR developments concepts, visit the following sites for SignalR source code and resources:

- SignalR Project
- SignalR Github and Samples

- SignalR Wiki

Tutorial: Getting Started with SignalR 1.x and MVC 4

2/20/2020 • 8 minutes to read • Edit Online

by Patrick Fletcher, Tim Teebken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This tutorial shows how to use ASP.NET SignalR to create a real-time chat application. You will add SignalR to an MVC 4 application and create a chat view to send and display messages.

Overview

This tutorial introduces you to real-time web application development with ASP.NET SignalR and ASP.NET MVC 4. The tutorial uses the same chat application code as the SignalR Getting Started tutorial, but shows how to add it to an MVC 4 application based on the Internet template.

In this topic you will learn the following SignalR development tasks:

- Adding the SignalR library to an MVC 4 application.
- Creating a hub class to push content to clients.
- Using the SignalR jQuery library in a web page to send messages and display updates from the hub.

The following screen shot shows the completed chat application running in a browser.

Sections:

- Set up the Project
- Run the Sample
- Examine the Code
- Next Steps

Set up the Project

Prerequisites:

- Visual Studio 2010 SP1, Visual Studio 2012, or Visual Studio 2012 Express. If you do not have Visual Studio, see ASP.NET Downloads to get the free Visual Studio 2012 Express Development Tool.
- For Visual Studio 2010, install ASP.NET MVC 4.

This section shows how to create an ASP.NET MVC 4 application, add the SignalR library, and create the chat application.

1. a. In Visual Studio create an ASP.NET MVC 4 application, name it SignalRChat, and click OK.

> **NOTE**
>
> In VS 2010, select **.NET Framework 4** in the Framework version dropdown control. SignalR code runs on .NET Framework versions 4 and 4.5.

2. Select the Internet Application template, clear the option to **Create a unit test project**, and click OK.

3. Open the **Tools > NuGet Package Manager > Package Manager Console** and run the following command. This step adds to the project a set of script files and assembly references that enable SignalR functionality.

`install-package Microsoft.AspNet.SignalR -Version 1.1.3` 4. In **Solution Explorer** expand the Scripts folder. Note that script libraries for SignalR have been added to the project.

5. In **Solution Explorer**, right-click the project, select **Add | New Folder**, and add a new folder named **Hubs**. 6. Right-click the **Hubs** folder, click **Add | Class**, and create a new C# class named **ChatHub.cs**. You will use this class as a SignalR server hub that sends messages to all clients.

> **NOTE**
>
> If you use Visual Studio 2012 and have installed the ASP.NET and Web Tools 2012.2 update, you can use the new SignalR item template to create the hub class. To do that, right-click the **Hubs** folder, click **Add | New Item**, select **SignalR Hub Class (v1)**, and name the class **ChatHub.cs**.

1. Replace the code in the **ChatHub** class with the following code.

```
using System;
using System.Web;
using Microsoft.AspNet.SignalR;

namespace SignalRChat
{
    public class ChatHub : Hub
    {
        public void Send(string name, string message)
        {
            // Call the addNewMessageToPage method to update clients.
            Clients.All.addNewMessageToPage(name, message);
        }
    }
}
```

2. Open the **Global.asax** file for the project, and add a call to the method `RouteTable.Routes.MapHubs();` as the first line of code in the `Application_Start` method. This code registers the default route for SignalR hubs and must be called before you register any other routes. The completed `Application_Start` method looks like the following example.

```
protected void Application_Start()
{
    RouteTable.Routes.MapHubs();
    AreaRegistration.RegisterAllAreas();

    WebApiConfig.Register(GlobalConfiguration.Configuration);
    FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
    RouteConfig.RegisterRoutes(RouteTable.Routes);
    BundleConfig.RegisterBundles(BundleTable.Bundles);
    AuthConfig.RegisterAuth();
}
```

3. Edit the `HomeController` class found in **Controllers/HomeController.cs** and add the following method to the class. This method returns the **Chat** view that you will create in a later step.

```
public ActionResult Chat()
{
    return View();
}
```

4. Right-click within the `Chat` method you just created, and click **Add View** to create a new view file.

5. In the **Add View** dialog, make sure the check box is selected to **Use a layout or master page** (clear the other check boxes), and then click **Add**.

6. Edit the new view file named **Chat.cshtml**. After the <h2> tag, paste the following section and `@section scripts` code block into the page. This script enables the page to send chat messages and display messages from the server. The complete code for the chat view appears in the following code block.

> **IMPORTANT**
>
> When you add SignalR and other script libraries to your Visual Studio project, the Package Manager might install versions of the scripts that are more recent than the versions shown in this topic. Make sure that the script references in your code match the versions of the script libraries installed in your project.

```
@{
    ViewBag.Title = "Chat";
}

<h2>Chat</h2>

<div class="container">
    <input type="text" id="message" />
    <input type="button" id="sendmessage" value="Send" />
    <input type="hidden" id="displayname" />
    <ul id="discussion">
    </ul>
</div>

@section scripts {
    <!--Script references. -->
    <!--The jQuery library is required and is referenced by default in _Layout.cshtml. -->
    <!--Reference the SignalR library. -->
    <script src="~/Scripts/jquery.signalR-1.0.1.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="~/signalr/hubs"></script>
    <!--SignalR script to update the chat page and send messages.-->
    <script>
        $(function () {
            // Reference the auto-generated proxy for the hub.
            var chat = $.connection.chatHub;
            // Create a function that the hub can call back to display messages.
            chat.client.addNewMessageToPage = function (name, message) {
                // Add the message to the page.
                $('#discussion').append('<li><strong>' + htmlEncode(name)
                    + '</strong>: ' + htmlEncode(message) + '</li>');
            };
            // Get the user name and store it to prepend to messages.
            $('#displayname').val(prompt('Enter your name:', ''));
            // Set initial focus to message input box.
            $('#message').focus();
            // Start the connection.
            $.connection.hub.start().done(function () {
                $('#sendmessage').click(function () {
                    // Call the Send method on the hub.
                    chat.server.send($('#displayname').val(), $('#message').val());
                    // Clear text box and reset focus for next comment.
                    $('#message').val('').focus();
                });
            });
        });
        // This optional function html-encodes messages for display in the page.
        function htmlEncode(value) {
            var encodedValue = $('<div />').text(value).html();
            return encodedValue;
        }
    </script>
}
```

7. **Save All** for the project.

Run the Sample

1. Press F5 to run the project in debug mode.
2. In the browser address line, append **/home/chat** to the URL of the default page for the project. The Chat page loads in a browser instance and prompts for a user name.

3. Enter a user name.

4. Copy the URL from the address line of the browser and use it to open two more browser instances. In each browser instance, enter a unique user name.

5. In each browser instance, add a comment and click **Send**. The comments should display in all browser instances.

> **NOTE**
>
> This simple chat application does not maintain the discussion context on the server. The hub broadcasts comments to all current users. Users who join the chat later will see messages added from the time they join.

6. The following screen shot shows the chat application running in a browser.

7. In **Solution Explorer**, inspect the **Script Documents** node for the running application. This node is visible in debug mode if you are using Internet Explorer as your browser. There is a script file named **hubs** that the SignalR library dynamically generates at runtime. This file manages the communication between jQuery script and server-side code. If you use a browser other than Internet Explorer, you can also access the dynamic **hubs** file by browsing to it directly, for example http://mywebsite/signalr/hubs.

Examine the Code

The SignalR chat application demonstrates two basic SignalR development tasks: creating a hub as the main coordination object on the server, and using the SignalR jQuery library to send and receive messages.

SignalR Hubs

In the code sample the **ChatHub** class derives from the **Microsoft.AspNet.SignalR.Hub** class. Deriving from the **Hub** class is a useful way to build a SignalR application. You can create public methods on your hub class and then access those methods by calling them from jQuery scripts in a web page.

In the chat code, clients call the **ChatHub.Send** method to send a new message. The hub in turn sends the message to all clients by calling **Clients.All.addNewMessageToPage**.

The **Send** method demonstrates several hub concepts :

- Declare public methods on a hub so that clients can call them.
- Use the **Microsoft.AspNet.SignalR.Hub.Clients** property to access all clients connected to this hub.
- Call a jQuery function on the client (such as the `addNewMessageToPage` function) to update clients.

```
public class ChatHub : Hub
{
    public void Send(string name, string message)
    {
        Clients.All.addNewMessageToPage(name, message);
    }
}
```

SignalR and jQuery

The **Chat.cshtml** view file in the code sample shows how to use the SignalR jQuery library to communicate with a SignalR hub. The essential tasks in the code are creating a reference to the auto-generated proxy for the hub, declaring a function that the server can call to push content to clients, and starting a connection to send messages to the hub.

The following code declares a proxy for a hub.

```
var chat = $.connection.chatHub;
```

> **NOTE**
> In jQuery the reference to the server class and its members is in camel case. The code sample references the C# **ChatHub** class in jQuery as **chatHub**. If you want to reference the `ChatHub` class in jQuery with conventional Pascal casing as you would in C#, edit the ChatHub.cs class file. Add a `using` statement to reference the `Microsoft.AspNet.SignalR.Hubs` namespace. Then add the `HubName` attribute to the `ChatHub` class, for example `[HubName("ChatHub")]`. Finally, update your jQuery reference to the `ChatHub` class.

The following code shows how to create a callback function in the script. The hub class on the server calls this

function to push content updates to each client. The optional call to the `htmlEncode` function shows a way to HTML encode the message content before displaying it in the page, as a way to prevent script injection.

```
chat.client.addNewMessageToPage = function (name, message) {
    // Add the message to the page.
    $('#discussion').append('<li><strong>' + htmlEncode(name)
        + '</strong>: ' + htmlEncode(message) + '</li>');
};
```

The following code shows how to open a connection with the hub. The code starts the connection and then passes it a function to handle the click event on the **Send** button in the Chat page.

> **NOTE**
>
> This approach ensures that the connection is established before the event handler executes.

```
$.connection.hub.start().done(function () {
    $('#sendmessage').click(function () {
        // Call the Send method on the hub.
        chat.server.send($('#displayname').val(), $('#message').val());
        // Clear text box and reset focus for next comment.
        $('#message').val('').focus();
    });
});
```

Next Steps

You learned that SignalR is a framework for building real-time web applications. You also learned several SignalR development tasks: how to add SignalR to an ASP.NET application, how to create a hub class, and how to send and receive messages from the hub.

To learn more advanced SignalR developments concepts, visit the following sites for SignalR source code and resources :

High-Frequency Realtime with SignalR 1.x

2/20/2020 • 13 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This tutorial shows how to create a web application that uses ASP.NET SignalR to provide high-frequency messaging functionality. High-frequency messaging in this case means updates that are sent at a fixed rate; in the case of this application, up to 10 messages a second.

The application you'll create in this tutorial displays a shape that users can drag. The position of the shape in all other connected browsers will then be updated to match the position of the dragged shape using timed updates.

Concepts introduced in this tutorial have applications in real-time gaming and other simulation applications.

Comments on the tutorial are welcome. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This tutorial demonstrates how to create an application that shares the state of an object with other browsers in real time. The application we'll create is called MoveShape. The MoveShape page will display an HTML Div element that the user can drag; when the user drags the Div, its new position will be sent to the server, which will then tell all other connected clients to update the shape's position to match.

The application created in this tutorial is based on a demo by Damian Edwards. A video containing this demo can be seen here.

The tutorial will start by demonstrating how to send SignalR messages from each event that fires as the shape is dragged. Each connected client will then update the position of the local version of the shape each time a message is received.

While the application will function using this method, this is not a recommended programming model, since there would be no upper limit to the number of messages getting sent, so the clients and server could get overwhelmed with messages and performance would degrade. The displayed animation on the client would also be disjointed, as the shape would be moved instantly by each method, rather than moving smoothly to each new location. Later sections of the tutorial will demonstrate how to create a timer function that restricts the maximum rate at which messages are sent by either the client or server, and how to move the shape smoothly between locations. The final version of the application created in this tutorial can be downloaded from Code Gallery.

This tutorial contains the following sections:

- Prerequisites
- Create the project
- Add the ASP.NET SignalR and JQuery.UI NuGet packages
- Create the base application
- Add the client loop
- Add the server loop
- Add smooth animation on the client
- Further Steps

Prerequisites

This tutorial requires Visual Studio 2012 or Visual Studio 2010. If Visual Studio 2010 is used, the project will use .NET Framework 4 rather than .NET Framework 4.5.

If you are using Visual Studio 2012, it's recommended that you install the ASP.NET and Web Tools 2012.2 update. This update contains new features such as enhancements to publishing, new functionality, and new templates.

If you have Visual Studio 2010, make sure that NuGet is installed.

Create the project

In this section, we'll create the project in Visual Studio.

1. From the **File** menu click **New Project**.
2. In the **New Project** dialog box, expand **C#** under **Templates** and select **Web**.
3. Select the **ASP.NET Empty Web Application** template, name the project *MoveShapeDemo*, and click **OK**.

Add the SignalR and JQuery.UI NuGet Packages

You can add SignalR functionality to a project by installing a NuGet package. This tutorial will also use the JQuery.UI package for allowing the shape to be dragged and animated.

1. Click **Tools | NuGet Package Manager | Package Manager Console**.

2. Enter the following command in the package manager.

   ```
   Install-Package Microsoft.AspNet.SignalR -Version 1.1.3
   ```

   The SignalR package installs a number of other NuGet packages as dependencies. When the installation is finished you have all of the server and client components required to use SignalR in an ASP.NET application.

3. Enter the following command into the package manager console to install the JQuery and JQuery.UI packages.

   ```
   Install-Package jQuery.ui.combined
   ```

Create the base application

In this section, we'll create a browser application that sends the location of the shape to the server during each mouse move event. The server then broadcasts this information to all other connected clients as it is received. We'll expand on this application in later sections.

1. In **Solution Explorer**, right-click on the project and select **Add**, **Class...**. Name the class **MoveShapeHub** and click **Add**.

2. Replace the code in the new **MoveShapeHub** class with the following code.

```
using System;
using System.Collections.Generic;
using System.Linq;
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;
using Newtonsoft.Json;

namespace MoveShapeDemo
{
    public class MoveShapeHub : Hub
    {
        public void UpdateModel(ShapeModel clientModel)
        {
            clientModel.LastUpdatedBy = Context.ConnectionId;
            // Update the shape model within our broadcaster
            Clients.AllExcept(clientModel.LastUpdatedBy).updateShape(clientModel);
        }
    }
    public class ShapeModel
    {
        // We declare Left and Top as lowercase with
        // JsonProperty to sync the client and server models
        [JsonProperty("left")]
        public double Left { get; set; }

        [JsonProperty("top")]
        public double Top { get; set; }

        // We don't want the client to get the "LastUpdatedBy" property
        [JsonIgnore]
        public string LastUpdatedBy { get; set; }
    }
}
```

The `MoveShapeHub` class above is an implementation of a SignalR hub. As in the Getting Started with SignalR tutorial, the hub has a method that the clients will call directly. In this case, the client will send an object containing the new X and Y coordinates of the shape to the server, which then gets broadcasted to all other connected clients. SignalR will automatically serialize this object using JSON.

The object that will be sent to the client (`ShapeModel`) contains members to store the position of the shape. The version of the object on the server also contains a member to track which client's data is being stored, so that a given client won't be sent their own data. This member uses the `JsonIgnore` attribute to keep it from being serialized and sent to the client.

3. Next, we'll set up the hub when the application starts. In **Solution Explorer**, right-click the project, then click **Add | Global Application Class**. Accept the default name of *Global* and click **OK**.

4. Add the following `using` statement after the provided **using** statements in the Global.asax.cs class.

```
using System.Web.Routing;
```

5. Add the following line of code in the `Application_Start` method of the Global class to register the default route for SignalR.

```
RouteTable.Routes.MapHubs();
```

Your global.asax file should look like the following:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Security;
using System.Web.SessionState;

using System.Web.Routing;

namespace MoveShapeDemo
{
    public class Global : System.Web.HttpApplication
    {
        protected void Application_Start(object sender, EventArgs e)
        {
            RouteTable.Routes.MapHubs();
        }
    }
}
```

6. Next, we'll add the client. In **Solution Explorer**, right-click the project, then click **Add | New Item**. In the **Add New Item** dialog, select **Html Page**. Give the page an appropriate name (like **Default.html**) and click **Add**.

7. In **Solution Explorer**, right-click the page you just created and click **Set as Start Page**.

8. Replace the default code in the HTML page with the following code snippet.

> **NOTE**
>
> Verify that the script references below match the packages added to your project in the Scripts folder. In Visual Studio 2010, the version of JQuery and SignalR added to the project may not match the version numbers below.

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR MoveShape Demo</title>
    <style>
        #shape {
            width: 100px;
            height: 100px;
            background-color: #FF0000;
        }
    </style>
</head>
<body>
<script src="Scripts/jquery-1.6.4.js"></script>
<script src="Scripts/jquery-ui-1.10.2.js"></script>
<script src="Scripts/jquery.signalR-1.0.1.js"></script>
<script src="/signalr/hubs"></script>
<script>
 $(function () {
            var moveShapeHub = $.connection.moveShapeHub,
            $shape = $("#shape"),

            shapeModel = {
                left: 0,
                top: 0
            };

            moveShapeHub.client.updateShape = function (model) {
                shapeModel = model;
                $shape.css({ left: model.left, top: model.top });
            };

            $.connection.hub.start().done(function () {
                $shape.draggable({
                    drag: function () {
                        shapeModel = $shape.offset();
                        moveShapeHub.server.updateModel(shapeModel);
                    }
                });
            });
        });
</script>

    <div id="shape" />
</body>
</html>
```

The above HTML and JavaScript code creates a red Div called Shape, enables the shape's dragging behavior using the jQuery library, and uses the shape's `drag` event to send the shape's position to the server.

9. Start the application by pressing F5. Copy the page's URL, and paste it into a second browser window. Drag the shape in one of the browser windows; the shape in the other browser window should move.

Add the client loop

Since sending the location of the shape on every mouse move event will create an unnecessary amount of network traffic, the messages from the client need to be throttled. We'll use the javascript `setInterval` function to set up a loop that sends new position information to the server at a fixed rate. This loop is a very basic representation of a "game loop", a repeatedly called function that drives all of the functionality of a game or other simulation.

1. Update the client code in the HTML page to match the following code snippet.

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR MoveShape Demo</title>
    <style>
        #shape {
            width: 100px;
            height: 100px;
            background-color: #FF0000;
        }
    </style>

</head>
<body>
<script src="Scripts/jquery-1.6.4.js"></script>
<script src="Scripts/jquery-ui-1.10.2.js"></script>
<script src="Scripts/jquery.signalR-1.0.1.js"></script>
<script src="/signalr/hubs"></script>
<script>
        $(function () {
            var moveShapeHub = $.connection.moveShapeHub,
                $shape = $("#shape"),
                // Send a maximum of 10 messages per second
                // (mouse movements trigger a lot of messages)
                messageFrequency = 10,
                // Determine how often to send messages in
                // time to abide by the messageFrequency
                updateRate = 1000 / messageFrequency,
                shapeModel = {
                    left: 0,
                    top: 0
                },
                moved = false;

            moveShapeHub.client.updateShape = function (model) {
                shapeModel = model;
                $shape.css({ left: model.left, top: model.top });
            };

            $.connection.hub.start().done(function () {
                $shape.draggable({
                    drag: function () {
                        shapeModel = $shape.offset();
                        moved = true;
                    }
                });

                // Start the client side server update interval
                setInterval(updateServerModel, updateRate);
            });

            function updateServerModel() {
                // Only update server if we have a new movement
                if (moved) {
                    moveShapeHub.server.updateModel(shapeModel);
                    moved = false;
                }
            }
        });
</script>

    <div id="shape" />
</body>
</html>
```

The above update adds the `updateServerModel` function, which gets called on a fixed frequency. This

function sends the position data to the server whenever the `moved` flag indicates that there is new position data to send.

2. Start the application by pressing F5. Copy the page's URL, and paste it into a second browser window. Drag the shape in one of the browser windows; the shape in the other browser window should move. Since the number of messages that get sent to the server will be throttled, the animation will not appear as smooth as in the previous section.

Add the server loop

In the current application, messages sent from the server to the client go out as often as they are received. This presents a similar problem as was seen on the client; messages can be sent more often than they are needed, and the connection could become flooded as a result. This section describes how to update the server to implement a timer that throttles the rate of the outgoing messages.

1. Replace the contents of `MoveShapeHub.cs` with the following code snippet.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;

using System.Threading;
using Microsoft.AspNet.SignalR;

using Newtonsoft.Json;

namespace MoveShapeDemo
{
    public class Broadcaster
    {
        private readonly static Lazy<Broadcaster> _instance =
            new Lazy<Broadcaster>(() => new Broadcaster());
        // We're going to broadcast to all clients a maximum of 25 times per second
        private readonly TimeSpan BroadcastInterval =
            TimeSpan.FromMilliseconds(40);
        private readonly IHubContext _hubContext;
        private Timer _broadcastLoop;
        private ShapeModel _model;
```

```
        private bool _modelUpdated;

        public Broadcaster()
        {
            // Save our hub context so we can easily use it
            // to send to its connected clients
            _hubContext = GlobalHost.ConnectionManager.GetHubContext<MoveShapeHub>();

            _model = new ShapeModel();
            _modelUpdated = false;

            // Start the broadcast loop
            _broadcastLoop = new Timer(
                BroadcastShape,
                null,
                BroadcastInterval,
                BroadcastInterval);
        }

        public void BroadcastShape(object state)
        {
            // No need to send anything if our model hasn't changed
            if (_modelUpdated)
            {
                // This is how we can access the Clients property
                // in a static hub method or outside of the hub entirely
                _hubContext.Clients.AllExcept(_model.LastUpdatedBy).updateShape(_model);
                _modelUpdated = false;
            }
        }

        public void UpdateShape(ShapeModel clientModel)
        {
            _model = clientModel;
            _modelUpdated = true;
        }

        public static Broadcaster Instance
        {
            get
            {
                return _instance.Value;
            }
        }
    }

    public class MoveShapeHub : Hub
    {
        // Is set via the constructor on each creation
        private Broadcaster _broadcaster;

        public MoveShapeHub()
            : this(Broadcaster.Instance)
        {
        }

        public MoveShapeHub(Broadcaster broadcaster)
        {
            _broadcaster = broadcaster;
        }

        public void UpdateModel(ShapeModel clientModel)
        {
            clientModel.LastUpdatedBy = Context.ConnectionId;
            // Update the shape model within our broadcaster
            _broadcaster.UpdateShape(clientModel);
        }
    }
    public class ShapeModel
```

```
    {
        // We declare Left and Top as lowercase with
        // JsonProperty to sync the client and server models
        [JsonProperty("left")]
        public double Left { get; set; }

        [JsonProperty("top")]
        public double Top { get; set; }

        // We don't want the client to get the "LastUpdatedBy" property
        [JsonIgnore]
        public string LastUpdatedBy { get; set; }
    }

}
```

The above code expands the client to add the `Broadcaster` class, which throttles the outgoing messages using the `Timer` class from the .NET framework.

Since the hub itself is transitory (it is created every time it is needed), the `Broadcaster` will be created as a singleton. Lazy initialization (introduced in .NET 4) is used to defer its creation until it is needed, ensuring that the first hub instance is completely created before the timer is started.

The call to the clients' `UpdateShape` function is then moved out of the hub's `UpdateModel` method, so that it is no longer called immediately whenever incoming messages are received. Instead, the messages to the clients will be sent at a rate of 25 calls per second, managed by the `_broadcastLoop` timer from within the `Broadcaster` class.

Lastly, instead of calling the client method from the hub directly, the `Broadcaster` class needs to obtain a reference to the currently operating hub (`_hubContext`) using the `GlobalHost`.

2. Start the application by pressing F5. Copy the page's URL, and paste it into a second browser window. Drag the shape in one of the browser windows; the shape in the other browser window should move. There will not be a visible difference in the browser from the previous section, but the number of messages that get sent to the client will be throttled.

Add smooth animation on the client

The application is almost complete, but we could make one more improvement, in the motion of the shape on the client as it is moved in response to server messages. Rather than setting the position of the shape to the new location given by the server, we'll use the JQuery UI library's `animate` function to move the shape smoothly between its current and new position.

1. Update the client's `updateShape` method to look like the highlighted code below:

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR MoveShape Demo</title>
    <style>
        #shape {
            width: 100px;
            height: 100px;
            background-color: #FF0000;
        }
    </style>

</head>
<body>
<script src="Scripts/jquery-1.6.4.js"></script>
<script src="Scripts/jquery-ui-1.10.2.js"></script>
<script src="Scripts/jquery.signalR-1.0.1.js"></script>
<script src="/signalr/hubs"></script>
<script>
        $(function () {
            var moveShapeHub = $.connection.moveShapeHub,
                $shape = $("#shape"),
                // Send a maximum of 10 messages per second
                // (mouse movements trigger a lot of messages)
                messageFrequency = 10,
                // Determine how often to send messages in
                // time to abide by the messageFrequency
                updateRate = 1000 / messageFrequency,
                shapeModel = {
                    left: 0,
                    top: 0
                },
                moved = false;

             moveShapeHub.client.updateShape = function (model) {
                 shapeModel = model;
                 // Gradually move the shape towards the new location (interpolate)
                 // The updateRate is used as the duration because by the time
                 // we get to the next location we want to be at the "last" location
                 // We also clear the animation queue so that we start a new
                 // animation and don't lag behind.
                 $shape.animate(shapeModel, { duration: updateRate, queue: false });
            };

            $.connection.hub.start().done(function () {
                $shape.draggable({
                    drag: function () {
                        shapeModel = $shape.offset();
                        moved = true;
                    }
                });

                // Start the client side server update interval
                setInterval(updateServerModel, updateRate);
            });

            function updateServerModel() {
                // Only update server if we have a new movement
                if (moved) {
                    moveShapeHub.server.updateModel(shapeModel);
```

```
                    moved = false;
                }
            }
        });
</script>

    <div id="shape" />
</body>
</html>
```

The above code moves the shape from the old location to the new one given by the server over the course of the animation interval (in this case, 100 milliseconds). Any previous animation running on the shape is cleared before the new animation starts.

2. Start the application by pressing F5. Copy the page's URL, and paste it into a second browser window. Drag the shape in one of the browser windows; the shape in the other browser window should move. The movement of the shape in the other window should appear less jerky as its movement is interpolated over time rather than being set once per incoming message.

Further Steps

In this tutorial, you've learned how to program a SignalR application that sends high-frequency messages between clients and servers. This communication paradigm is useful for developing online games and other simulations, such as the ShootR game created with SignalR.

The complete application created in this tutorial can be downloaded from Code Gallery.

Tutorial: Server Broadcast with ASP.NET SignalR 1.x

2/20/2020 • 27 minutes to read • Edit Online

by Patrick Fletcher, Tom Dykstra

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This tutorial shows how to create a web application that uses ASP.NET SignalR to provide server broadcast functionality. Server broadcast means that communications sent to clients are initiated by the server. This scenario requires a different programming approach than peer-to-peer scenarios such as chat applications, in which communications sent to clients are initiated by one or more of the clients.

The application that you'll create in this tutorial simulates a stock ticker, a typical scenario for server broadcast functionality.

Comments on the tutorial are welcome. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

The Microsoft.AspNet.SignalR.Sample NuGet package installs a sample simulated stock ticker application in a Visual Studio project. In the first part of this tutorial, you'll create a simplified version of that application from scratch. In the remainder of the tutorial, you'll install the NuGet package and review the additional features and code that it creates.

The stock ticker application is a representative of a kind of real-time application in which you want to periodically "push," or broadcast, notifications from the server to all connected clients.

The application that you'll build in the first part of this tutorial displays a grid with stock data.

Periodically the server randomly updates stock prices and pushes the updates to all connected clients. In the browser the numbers and symbols in the **Change** and **%** columns dynamically change in response to notifications from the server. If you open additional browsers to the same URL, they all show the same data and the same changes to the data simultaneously.

This tutorial contains the following sections:

- Prerequisites
- Create the project
- Add the SignalR NuGet packages
- Set up the server code
- Set up the client code
- Test the application
- Enable logging
- Install and review the full StockTicker sample
- Next steps

> **NOTE**
>
> If you don't want to work through the steps of building the application, you can install the SignalR.Sample package in a new **Empty ASP.NET Web Application** project, and read through these steps to get explanations of the code. The first part of the tutorial covers a subset of the SignalR.Sample code, and the second part explains key features of the additional functionality in the SignalR.Sample package.

Prerequisites

Before you start, make sure that you have Visual Studio 2012 or 2010 SP1 installed on your computer. If you don't have Visual Studio, see ASP.NET Downloads to get the free Visual Studio 2012 Express for Web.

If you have Visual Studio 2010, make sure that NuGet is installed.

Create the project

1. From the **File** menu click **New Project**.
2. In the **New Project** dialog box, expand **C#** under **Templates** and select **Web**.
3. Select the **ASP.NET Empty Web Application** template, name the project *SignalR.StockTicker*, and click **OK**.

Add the SignalR NuGet Packages

Add the SignalR and JQuery NuGet Packages

You can add SignalR functionality to a project by installing a NuGet package.

1. Click **Tools | NuGet Package Manager | Package Manager Console**.
2. Enter the following command in the package manager.

   ```
   Install-Package Microsoft.AspNet.SignalR -Version 1.1.3
   ```

   The SignalR package installs a number of other NuGet packages as dependencies. When the installation is finished you have all of the server and client components required to use SignalR in an ASP.NET application.

Set up the server code

In this section you set up the code that runs on the server.

Create the Stock class

You begin by creating the Stock model class that you'll use to store and transmit information about a stock.

1. Create a new class file in the project folder, name it *Stock.cs*, and then replace the template code with the following code:

```
using System;

namespace SignalR.StockTicker
{
    public class Stock
    {
        private decimal _price;

        public string Symbol { get; set; }

        public decimal Price
        {
            get
            {
                return _price;
            }
            set
            {
                if (_price == value)
                {
                    return;
                }

                _price = value;

                if (DayOpen == 0)
                {
                    DayOpen = _price;
                }
            }
        }

        public decimal DayOpen { get; private set; }

        public decimal Change
        {
            get
            {
                return Price - DayOpen;
            }
        }

        public double PercentChange
        {
            get
            {
                return (double)Math.Round(Change / Price, 4);
            }
        }
    }
}
```

The two properties that you'll set when you create stocks are the Symbol (for example, MSFT for Microsoft) and the Price. The other properties depend on how and when you set Price. The first time you set Price, the value gets propagated to DayOpen. Subsequent times when you set Price, the Change and PercentChange property values are calculated based on the difference between Price and DayOpen.

Create the StockTicker and StockTickerHub classes

You'll use the SignalR Hub API to handle server-to-client interaction. A StockTickerHub class that derives from the SignalR Hub class will handle receiving connections and method calls from clients. You also need to maintain stock data and run a Timer object to periodically trigger price updates, independently of client connections. You can't put these functions in a Hub class, because Hub instances are transient. A Hub class instance is created for each operation on the hub, such as connections and calls from the client to the server. So the mechanism that keeps

stock data, updates prices, and broadcasts the price updates has to run in a separate class, which you'll name StockTicker.

You only want one instance of the StockTicker class to run on the server, so you'll need to set up a reference from each StockTickerHub instance to the singleton StockTicker instance. The StockTicker class has to be able to broadcast to clients because it has the stock data and triggers updates, but StockTicker is not a Hub class. Therefore, the StockTicker class has to get a reference to the SignalR Hub connection context object. It can then use the SignalR connection context object to broadcast to clients.

1. In **Solution Explorer**, right-click the project and click **Add New Item**.
2. If you have Visual Studio 2012 with the ASP.NET and Web Tools 2012.2 Update, click **Web** under **Visual C#** and select the **SignalR Hub Class** item template. Otherwise, select the **Class** template.
3. Name the new class *StockTickerHub.cs*, and then click **Add**.

4. Replace the template code with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;

namespace SignalR.StockTicker
{
    [HubName("stockTickerMini")]
    public class StockTickerHub : Hub
    {
        private readonly StockTicker _stockTicker;

        public StockTickerHub() : this(StockTicker.Instance) { }

        public StockTickerHub(StockTicker stockTicker)
        {
            _stockTicker = stockTicker;
        }

        public IEnumerable<Stock> GetAllStocks()
        {
            return _stockTicker.GetAllStocks();
        }
    }
}
```

The Hub class is used to define methods the clients can call on the server. You are defining one method: `GetAllStocks()`. When a client initially connects to the server, it will call this method to get a list of all of the stocks with their current prices. The method can execute synchronously and return `IEnumerable<Stock>` because it is returning data from memory. If the method had to get the data by doing something that would involve waiting, such as a database lookup or a web service call, you would specify `Task<IEnumerable<Stock>>` as the return value to enable asynchronous processing. For more information, see ASP.NET SignalR Hubs API Guide - Server - When to execute asynchronously.

The HubName attribute specifies how the Hub will be referenced in JavaScript code on the client. The default name on the client if you don't use this attribute is a camel-cased version of the class name, which in this case would be stockTickerHub.

As you'll see later when you create the StockTicker class, a singleton instance of that class is created in its static Instance property. That singleton instance of StockTicker remains in memory no matter how many clients connect or disconnect, and that instance is what the GetAllStocks method uses to return current stock information.

5. Create a new class file in the project folder, name it *StockTicker.cs*, and then replace the template code with the following code:

```
using System;
using System.Collections.Concurrent;
using System.Collections.Generic;
using System.Threading;
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;

namespace SignalR.StockTicker
{
    public class StockTicker
    {
        // Singleton instance
        private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(() => new
StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));
```

```
        private readonly ConcurrentDictionary<string, Stock> _stocks = new ConcurrentDictionary<string,
Stock>();

        private readonly object _updateStockPricesLock = new object();

        //stock can go up or down by a percentage of this factor on each change
        private readonly double _rangePercent = .002;

        private readonly TimeSpan _updateInterval = TimeSpan.FromMilliseconds(250);
        private readonly Random _updateOrNotRandom = new Random();

        private readonly Timer _timer;
        private volatile bool _updatingStockPrices = false;

        private StockTicker(IHubConnectionContext clients)
        {
            Clients = clients;

            _stocks.Clear();
            var stocks = new List<Stock>
            {
                new Stock { Symbol = "MSFT", Price = 30.31m },
                new Stock { Symbol = "APPL", Price = 578.18m },
                new Stock { Symbol = "GOOG", Price = 570.30m }
            };
            stocks.ForEach(stock => _stocks.TryAdd(stock.Symbol, stock));

            _timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);

        }

        public static StockTicker Instance
        {
            get
            {
                return _instance.Value;
            }
        }

        private IHubConnectionContext Clients
        {
            get;
            set;
        }

        public IEnumerable<Stock> GetAllStocks()
        {
            return _stocks.Values;
        }

        private void UpdateStockPrices(object state)
        {
            lock (_updateStockPricesLock)
            {
                if (!_updatingStockPrices)
                {
                    _updatingStockPrices = true;

                    foreach (var stock in _stocks.Values)
                    {
                        if (TryUpdateStockPrice(stock))
                        {
                            BroadcastStockPrice(stock);
                        }
                    }

                    _updatingStockPrices = false;
                }
```

```
            }
        }

        private bool TryUpdateStockPrice(Stock stock)
        {
            // Randomly choose whether to udpate this stock or not
            var r = _updateOrNotRandom.NextDouble();
            if (r > .1)
            {
                return false;
            }

            // Update the stock price by a random factor of the range percent
            var random = new Random((int)Math.Floor(stock.Price));
            var percentChange = random.NextDouble() * _rangePercent;
            var pos = random.NextDouble() > .51;
            var change = Math.Round(stock.Price * (decimal)percentChange, 2);
            change = pos ? change : -change;

            stock.Price += change;
            return true;
        }

        private void BroadcastStockPrice(Stock stock)
        {
            Clients.All.updateStockPrice(stock);
        }

    }
}
```

Since multiple threads will be running the same instance of StockTicker code, the StockTicker class has to be threadsafe.

Storing the singleton instance in a static field

The code initializes the static _instance field that backs the Instance property with an instance of the class, and this is the only instance of the class that can be created, because the constructor is marked as private. Lazy initialization is used for the _instance field, not for performance reasons but to ensure that the instance creation is threadsafe.

```
private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(() => new
StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));

public static StockTicker Instance
{
    get
    {
        return _instance.Value;
    }
}
```

Each time a client connects to the server, a new instance of the StockTickerHub class running in a separate thread gets the StockTicker singleton instance from the StockTicker.Instance static property, as you saw earlier in the StockTickerHub class.

Storing stock data in a ConcurrentDictionary

The constructor initializes the _stocks collection with some sample stock data, and GetAllStocks returns the stocks. As you saw earlier, this collection of stocks is in turn returned by StockTickerHub.GetAllStocks which is a server method in the Hub class that clients can call.

```
private readonly ConcurrentDictionary<string, Stock> _stocks = new ConcurrentDictionary<string, Stock>
();
```

```
private StockTicker(IHubConnectionContext clients)
{
    Clients = clients;

    _stocks.Clear();
    var stocks = new List<Stock>
    {
        new Stock { Symbol = "MSFT", Price = 30.31m },
        new Stock { Symbol = "APPL", Price = 578.18m },
        new Stock { Symbol = "GOOG", Price = 570.30m }
    };
    stocks.ForEach(stock => _stocks.TryAdd(stock.Symbol, stock));

    _timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);
}

public IEnumerable<Stock> GetAllStocks()
{
    return _stocks.Values;
}
```

The stocks collection is defined as a ConcurrentDictionary type for thread safety. As an alternative, you could use a Dictionary object and explicitly lock the dictionary when you make changes to it.

For this sample application, it's OK to store application data in memory and to lose the data when the StockTicker instance is disposed. In a real application you would work with a back-end data store such as a database.

Periodically updating stock prices

The constructor starts up a Timer object that periodically calls methods that update stock prices on a random basis.

```
_timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);

private void UpdateStockPrices(object state)
{
    lock (_updateStockPricesLock)
    {
        if (!_updatingStockPrices)
        {
            _updatingStockPrices = true;

            foreach (var stock in _stocks.Values)
            {
                if (TryUpdateStockPrice(stock))
                {
                    BroadcastStockPrice(stock);
                }
            }

            _updatingStockPrices = false;
        }
    }
}

private bool TryUpdateStockPrice(Stock stock)
{
    // Randomly choose whether to update this stock or not
    var r = _updateOrNotRandom.NextDouble();
    if (r > .1)
    {
        return false;
    }

    // Update the stock price by a random factor of the range percent
    var random = new Random((int)Math.Floor(stock.Price));
    var percentChange = random.NextDouble() * _rangePercent;
    var pos = random.NextDouble() > .51;
    var change = Math.Round(stock.Price * (decimal)percentChange, 2);
    change = pos ? change : -change;

    stock.Price += change;
    return true;
}
```

UpdateStockPrices is called by the Timer, which passes in null in the state parameter. Before updating prices, a lock is taken on the _updateStockPricesLock object. The code checks if another thread is already updating prices, and then it calls TryUpdateStockPrice on each stock in the list. The TryUpdateStockPrice method decides whether to change the stock price, and how much to change it. If the stock price is changed, BroadcastStockPrice is called to broadcast the stock price change to all connected clients.

The _updatingStockPrices flag is marked as volatile to ensure that access to it is threadsafe.

```
private volatile bool _updatingStockPrices = false;
```

In a real application, the TryUpdateStockPrice method would call a web service to look up the price; in this code it uses a random number generator to make changes randomly.

Getting the SignalR context so that the StockTicker class can broadcast to clients

Because the price changes originate here in the StockTicker object, this is the object that needs to call an updateStockPrice method on all connected clients. In a Hub class you have an API for calling client methods, but StockTicker does not derive from the Hub class and does not have a reference to any Hub object. Therefore, in order to broadcast to connected clients, the StockTicker class has to get the SignalR context

instance for the StockTickerHub class and use that to call methods on clients.

The code gets a reference to the SignalR context when it creates the singleton class instance, passes that reference to the constructor, and the constructor puts it in the Clients property.

There are two reasons why you want to get the context just once: getting the context is an expensive operation, and getting it once ensures that the intended order of messages sent to clients is preserved.

```
private readonly static Lazy<StockTicker> _instance =
    new Lazy<StockTicker>(() => new
StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));

private StockTicker(IHubConnectionContext clients)
{
    Clients = clients;

    // Remainder of constructor ...
}

private IHubConnectionContext Clients
{
    get;
    set;
}

private void BroadcastStockPrice(Stock stock)
{
    Clients.All.updateStockPrice(stock);
}
```

Getting the Clients property of the context and putting it in the StockTickerClient property lets you write code to call client methods that looks the same as it would in a Hub class. For instance, to broadcast to all clients you can write Clients.All.updateStockPrice(stock).

The updateStockPrice method that you are calling in BroadcastStockPrice doesn't exist yet; you'll add it later when you write code that runs on the client. You can refer to updateStockPrice here because Clients.All is dynamic, which means the expression will be evaluated at runtime. When this method call executes, SignalR will send the method name and the parameter value to the client, and if the client has a method named updateStockPrice, that method will be called and the parameter value will be passed to it.

Clients.All means send to all clients. SignalR gives you other options to specify which clients or groups of clients to send to. For more information, see HubConnectionContext.

Register the SignalR route

The server needs to know which URL to intercept and direct to SignalR. To do that you'll add some code to the *Global.asax* file.

1. In **Solution Explorer**, right-click the project, and then click **Add New Item**.
2. Select the **Global Application Class** item template, and then click **Add**.

3. Add the SignalR route registration code to the Application_Start method:

```
protected void Application_Start(object sender, EventArgs e)
{
    RouteTable.Routes.MapHubs();
}
```

By default, the base URL for all SignalR traffic is "/signalr", and "/signalr/hubs" is used to retrieve a dynamically generated JavaScript file that defines proxies for all the Hubs you have in your application. The MapHubs method includes overloads that let you specify a different base URL and certain SignalR options in an instance of the HubConfiguration class.

4. Add a using statement at the top of the file:

```
using System.Web.Routing;
```

5. Save and close the *Global.asax* file, and build the project.

You have now completed setting up the server code. In the next section you'll set up the client.

Set up the client code

1. Create a new HTML file in the project folder, and name it *StockTicker.html*.

2. Replace the template code with the following code:

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>ASP.NET SignalR Stock Ticker</title>
    <style>
        body {
            font-family: 'Segoe UI', Arial, Helvetica, sans-serif;
            font-size: 16px;
        }
        #stockTable table {
            border-collapse: collapse;
        }
            #stockTable table th, #stockTable table td {
                padding: 2px 6px;
            }
            #stockTable table td {
                text-align: right;
            }
        #stockTable .loading td {
            text-align: left;
        }
    </style>
</head>
<body>
    <h1>ASP.NET SignalR Stock Ticker Sample</h1>

    <h2>Live Stock Table</h2>
    <div id="stockTable">
        <table border="1">
            <thead>
                <tr><th>Symbol</th><th>Price</th><th>Open</th><th>Change</th><th>%</th></tr>
            </thead>
            <tbody>
                <tr class="loading"><td colspan="5">loading...</td></tr>
            </tbody>
        </table>
    </div>

    <!--Script references. -->
    <!--Reference the jQuery library. -->
    <script src="/Scripts/jquery-1.8.2.min.js" ></script>
    <!--Reference the SignalR library. -->
    <script src="/Scripts/jquery.signalR-1.0.1.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="/signalr/hubs"></script>
    <!--Reference the StockTicker script. -->
    <script src="StockTicker.js"></script>
</body>
</html>
```

The HTML creates a table with 5 columns, a header row, and a data row with a single cell that spans all 5 columns. The data row displays "loading..." and will only be shown momentarily when the application starts. JavaScript code will remove that row and add in its place rows with stock data retrieved from the server.

The script tags specify the jQuery script file, the SignalR core script file, the SignalR proxies script file, and a StockTicker script file that you'll create later. The SignalR proxies script file, which specifies the "/signalr/hubs" URL, is dynamically generated and defines proxy methods for the methods on the Hub class, in this case for StockTickerHub.GetAllStocks. If you prefer, you can generate this JavaScript file manually by using SignalR Utilities and disable dynamic file creation in the MapHubs method call.

3. **IMPORTANT**

   Make sure that the JavaScript file references in *StockTicker.html* are correct. That is, make sure that the jQuery version in your script tag (1.8.2 in the example) is the same as the jQuery version in your project's *Scripts* folder, and make sure that the SignalR version in your script tag is the same as the SignalR version in your project's *Scripts* folder. Change the file names in the script tags if necessary.

4. In **Solution Explorer**, right-click *StockTicker.html*, and then click **Set as Start Page**.

5. Create a new JavaScript file in the project folder and name it *StockTicker.js*..

6. Replace the template code with the following code:

```
// A simple templating method for replacing placeholders enclosed in curly braces.
if (!String.prototype.supplant) {
    String.prototype.supplant = function (o) {
        return this.replace(/{([^{}]*)}/g,
            function (a, b) {
                var r = o[b];
                return typeof r === 'string' || typeof r === 'number' ? r : a;
            }
        );
    };
}

$(function () {

    var ticker = $.connection.stockTickerMini, // the generated client-side hub proxy
        up = '▲',
        down = '▼',
        $stockTable = $('#stockTable'),
        $stockTableBody = $stockTable.find('tbody'),
        rowTemplate = '<tr data-symbol="{Symbol}"><td>{Symbol}</td><td>{Price}</td><td>{DayOpen}</td>
<td>{Direction} {Change}</td><td>{PercentChange}</td></tr>';

    function formatStock(stock) {
        return $.extend(stock, {
            Price: stock.Price.toFixed(2),
            PercentChange: (stock.PercentChange * 100).toFixed(2) + '%',
            Direction: stock.Change === 0 ? '' : stock.Change >= 0 ? up : down
        });
    }

    function init() {
        ticker.server.getAllStocks().done(function (stocks) {
            $stockTableBody.empty();
            $.each(stocks, function () {
                var stock = formatStock(this);
                $stockTableBody.append(rowTemplate.supplant(stock));
            });
        });
    }

    // Add a client-side hub method that the server will call
    ticker.client.updateStockPrice = function (stock) {
        var displayStock = formatStock(stock),
            $row = $(rowTemplate.supplant(displayStock));

        $stockTableBody.find('tr[data-symbol=' + stock.Symbol + ']')
            .replaceWith($row);
        }

    // Start the connection
    $.connection.hub.start().done(init);

});
```

$.connection refers to the SignalR proxies. The code gets a reference to the proxy for the StockTickerHub class and puts it in the ticker variable. The proxy name is the name that was set by the [HubName] attribute:

```
var ticker = $.connection.stockTickerMini
```

```
[HubName("stockTickerMini")]
public class StockTickerHub : Hub
```

After all the variables and functions are defined, the last line of code in the file initializes the SignalR

connection by calling the SignalR start function. The start function executes asynchronously and returns a jQuery Deferred object, which means you can call the done function to specify the function to call when the asynchronous operation is completed..

```
$.connection.hub.start().done(init);
```

The init function calls the getAllStocks function on the server and uses the information that the server returns to update the stock table. Notice that by default, you have to use camel casing on the client although the method name is pascal-cased on the server. The camel-casing rule only applies to methods, not objects. For example, you refer to stock.Symbol and stock.Price, not stock.symbol or stock.price.

```
function init() {
    ticker.server.getAllStocks().done(function (stocks) {
        $stockTableBody.empty();
        $.each(stocks, function () {
            var stock = formatStock(this);
            $stockTableBody.append(rowTemplate.supplant(stock));
        });
    });
}
```

```
public IEnumerable<Stock> GetAllStocks()
{
    return _stockTicker.GetAllStocks();
}
```

If you wanted to use pascal casing on the client, or if you wanted to use a completely different method name, you could decorate the Hub method with the HubMethodName attribute the same way you decorated the Hub class itself with the HubName attribute.

In the init method, HTML for a table row is created for each stock object received from the server by calling formatStock to format properties of the stock object, and then by calling supplant (which is defined at the top of *StockTicker.js*) to replace placeholders in the rowTemplate variable with the stock object property values. The resulting HTML is then appended to the stock table.

You call init by passing it in as a callback function that executes after the asynchronous start function completes. If you called init as a separate JavaScript statement after calling start, the function would fail because it would execute immediately without waiting for the start function to finish establishing the connection. In that case, the init function would try to call the getAllStocks function before the server connection is established.

When the server changes a stock's price, it calls the updateStockPrice on connected clients. The function is added to the client property of the stockTicker proxy in order to make it available to calls from the server.

```
ticker.client.updateStockPrice = function (stock) {
    var displayStock = formatStock(stock),
        $row = $(rowTemplate.supplant(displayStock));

    $stockTableBody.find('tr[data-symbol=' + stock.Symbol + ']')
        .replaceWith($row);
    }
```

The updateStockPrice function formats a stock object received from the server into a table row the same way as in the init function. However, instead of appending the row to the table, it finds the stock's current row in the table and replaces that row with the new one.

Test the application

1. Press F5 to run the application in debug mode.

   The stock table initially displays the "loading..." line, then after a short delay the initial stock data is displayed, and then the stock prices start to change.

2. Copy the URL from the browser address bar and paste it into one or more new browser window(s).

   The initial stock display is the same as the first browser and changes happen simultaneously.

3. Close all browsers and open a new browser, then go to the same URL.

   The StockTicker singleton object has continued to run in the server, so the stock table display shows that the stocks have continued to change. (You don't see the initial table with zero change figures.)

4. Close the browser.

Enable logging

SignalR has a built-in logging function that you can enable on the client to aid in troubleshooting. In this section you enable logging and see examples that show how logs tell you which of the following transport methods SignalR is using:

- WebSockets, supported by IIS 8 and current browsers.
- Server-sent events, supported by browsers other than Internet Explorer.
- Forever frame, supported by Internet Explorer.
- Ajax long polling, supported by all browsers.

For any given connection, SignalR chooses the best transport method that both the server and the client support.

1. Open *StockTicker.js* and add a line of code to enable logging immediately before the code that initializes the connection at the end of the file:

```
// Start the connection
$.connection.hub.logging = true;
$.connection.hub.start().done(init);
```

2. Press F5 to run the project.

3. Open your browser's developer tools window, and select the Console to see the logs. You might have to refresh the page to see the logs of Signalr negotiating the transport method for a new connection.

   If you are running Internet Explorer 10 on Windows 8 (IIS 8), the transport method is WebSockets.

   If you are running Internet Explorer 10 on Windows 7 (IIS 7.5), the transport method is iframe.

In Firefox, install the Firebug add-in to get a Console window. If you are running Firefox 19 on Windows 8 (IIS 8), the transport method is WebSockets.

If you are running Firefox 19 on Windows 7 (IIS 7.5), the transport method is server-sent events.

Install and review the full StockTicker sample

The StockTicker application that is installed by the Microsoft.AspNet.SignalR.Sample NuGet package includes more features than the simplified version that you just created from scratch. In this section of the tutorial, you install the NuGet package and review the new features and the code that implements them.

Install the SignalR.Sample NuGet package

1. In **Solution Explorer**, right-click the project and click **Manage NuGet Packages**.
2. In the **Manage NuGet Packages** dialog box, click **Online**, enter *SignalR.Sample* in the **Search Online** box, and then click **Install** in the **SignalR.Sample** package.

3. In the *Global.asax* file, comment out the RouteTable.Routes.MapHubs(); line that you added earlier in the Application_Start method.

   The code in *Global.asax* is no longer needed because the SignalR.Sample package registers the SignalR route in the *App_Start/RegisterHubs.cs* file:

```
[assembly: WebActivator.PreApplicationStartMethod(typeof(SignalR.StockTicker.RegisterHubs), "Start")]

namespace SignalR.StockTicker
{
    public static class RegisterHubs
    {
        public static void Start()
        {
            // Register the default hubs route: ~/signalr/hubs
            RouteTable.Routes.MapHubs();
        }
    }
}
```

   The WebActivator class that is referenced by the assembly attribute is included in the WebActivatorEx NuGet package, which is installed as a dependency of the SignalR.Sample package.

4. In **Solution Explorer**, expand the *SignalR.Sample* folder which was created by installing the SignalR.Sample package.

5. In the *SignalR.Sample* folder, right-click *StockTicker.html*, and then click **Set As Start Page**.

> **NOTE**
>
> Installing The SignalR.Sample NuGet package might change the version of jQuery that you have in your *Scripts* folder. The new *StockTicker.html* file that the package installs in the *SignalR.Sample* folder will be in sync with the jQuery version that the package installs, but if you want to run your original *StockTicker.html* file again, you might have to update the jQuery reference in the script tag first.

Run the application

1. Press F5 to run the application.

   In addition to the grid that you saw earlier, the full stock ticker application shows a horizontally scrolling window that displays the same stock data. When you run the application for the first time, the "market" is "closed" and you see a static grid and a ticker window that isn't scrolling.

When you click **Open Market**, the **Live Stock Ticker** box starts to scroll horizontally, and the server starts to periodically broadcast stock price changes on a random basis. Each time a stock price changes, both the **Live Stock Table** grid and the **Live Stock Ticker** box are updated. When a stock's price change is positive, the stock is shown with a green background, and when the change is negative, the stock is shown with a red background.

The **Close Market** button stops the changes and stops the ticker scrolling, and the **Reset** button resets all stock data to the initial state before price changes started. If you open more browser windows and go to the same URL, you see the same data dynamically updated at the same time in each browser. When you click one of the buttons, all browsers respond the same way at the same time.

Live Stock Ticker display

The **Live Stock Ticker** display is an unordered list in a div element that is formatted into a single line by CSS styles. The ticker is initialized and updated the same way as the table: by replacing placeholders in a <li> template string and dynamically adding the <li> elements to the <ul> element. The scrolling is performed by using the jQuery animate function to vary the margin-left of the unordered list within the div.

The stock ticker HTML:

```
<h2>Live Stock Ticker</h2>
<div id="stockTicker">
    <div class="inner">
        <ul>
            <li class="loading">loading...</li>
        </ul>
    </div>
</div>
```

The stock ticker CSS:

```
#stockTicker {
    overflow: hidden;
    width: 450px;
    height: 24px;
    border: 1px solid #999;
    }

    #stockTicker .inner {
        width: 9999px;
    }

    #stockTicker ul {
        display: inline-block;
        list-style-type: none;
        margin: 0;
        padding: 0;
    }

    #stockTicker li {
        display: inline-block;
        margin-right: 8px;
    }

    /*<li data-symbol="{Symbol}"><span class="symbol">{Symbol}</span><span class="price">{Price}</span><span
class="change">{PercentChange}</span></li>*/
    #stockTicker .symbol {
        font-weight: bold;
    }

    #stockTicker .change {
        font-style: italic;
    }
```

The jQuery code that makes it scroll:

```
function scrollTicker() {
    var w = $stockTickerUl.width();
    $stockTickerUl.css({ marginLeft: w });
    $stockTickerUl.animate({ marginLeft: -w }, 15000, 'linear', scrollTicker);
}
```

Additional methods on the server that the client can call

The StockTickerHub class defines four additional methods that the client can call:

```
public string GetMarketState()
{
    return _stockTicker.MarketState.ToString();
}

public void OpenMarket()
{
    _stockTicker.OpenMarket();
}

public void CloseMarket()
{
    _stockTicker.CloseMarket();
}

public void Reset()
{
    _stockTicker.Reset();
}
```

OpenMarket, CloseMarket, and Reset are called in response to the buttons at the top of the page. They demonstrate the pattern of one client triggering a change in state that is immediately propagated to all clients. Each of these methods calls a method in the StockTicker class that effects the market state change and then broadcasts the new state.

In the StockTicker class, the state of the market is maintained by a MarketState property that returns a MarketState enum value:

```
public MarketState MarketState
{
    get { return _marketState; }
    private set { _marketState = value; }
}

public enum MarketState
{
    Closed,
    Open
}
```

Each of the methods that change the market state do so inside a lock block because the StockTicker class has to be threadsafe:

```
public void OpenMarket()
{
    lock (_marketStateLock)
    {
        if (MarketState != MarketState.Open)
        {
            _timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);
            MarketState = MarketState.Open;
            BroadcastMarketStateChange(MarketState.Open);
        }
    }
}

public void CloseMarket()
{
    lock (_marketStateLock)
    {
        if (MarketState == MarketState.Open)
        {
            if (_timer != null)
            {
                _timer.Dispose();
            }
            MarketState = MarketState.Closed;
            BroadcastMarketStateChange(MarketState.Closed);
        }
    }
}

public void Reset()
{
    lock (_marketStateLock)
    {
        if (MarketState != MarketState.Closed)
        {
            throw new InvalidOperationException("Market must be closed before it can be reset.");
        }
        LoadDefaultStocks();
        BroadcastMarketReset();
    }
}
```

To ensure that this code is threadsafe, the _marketState field that backs the MarketState property is marked as volatile,

```
private volatile MarketState _marketState;
```

The BroadcastMarketStateChange and BroadcastMarketReset methods are similar to the BroadcastStockPrice method that you already saw, except they call different methods defined at the client:

```
private void BroadcastMarketStateChange(MarketState marketState)
{
    switch (marketState)
    {
        case MarketState.Open:
            Clients.All.marketOpened();
            break;
        case MarketState.Closed:
            Clients.All.marketClosed();
            break;
        default:
            break;
    }
}

private void BroadcastMarketReset()
{
    Clients.All.marketReset();
}
```

Additional functions on the client that the server can call

The updateStockPrice function now handles both the grid and the ticker display, and it uses jQuery.Color to flash red and green colors.

New functions in *SignalR.StockTicker.js* enable and disable the buttons based on market state, and they stop or start the ticker window horizontal scrolling. Since multiple functions are being added to ticker.client, the jQuery extend function is used to add them.

```
$.extend(ticker.client, {
    updateStockPrice: function (stock) {
        var displayStock = formatStock(stock),
            $row = $(rowTemplate.supplant(displayStock)),
            $li = $(liTemplate.supplant(displayStock)),
            bg = stock.LastChange === 0
                ? '255,216,0' // yellow
                : stock.LastChange > 0
                    ? '154,240,117' // green
                    : '255,148,148'; // red

        $stockTableBody.find('tr[data-symbol=' + stock.Symbol + ']')
            .replaceWith($row);
        $stockTickerUl.find('li[data-symbol=' + stock.Symbol + ']')
            .replaceWith($li);

        $row.flash(bg, 1000);
        $li.flash(bg, 1000);
    },

    marketOpened: function () {
        $("#open").prop("disabled", true);
        $("#close").prop("disabled", false);
        $("#reset").prop("disabled", true);
        scrollTicker();
    },

    marketClosed: function () {
        $("#open").prop("disabled", false);
        $("#close").prop("disabled", true);
        $("#reset").prop("disabled", false);
        stopTicker();
    },

    marketReset: function () {
        return init();
    }
});
```

Additional client setup after establishing the connection

After the client establishes the connection, it has some additional work to do: find out if the market is open or closed in order to call the appropriate marketOpened or marketClosed function, and attach the server method calls to the buttons.

```
$.connection.hub.start()
    .pipe(init)
    .pipe(function () {
        return ticker.server.getMarketState();
    })
    .done(function (state) {
        if (state === 'Open') {
            ticker.client.marketOpened();
        } else {
            ticker.client.marketClosed();
        }

        // Wire up the buttons
        $("#open").click(function () {
            ticker.server.openMarket();
        });

        $("#close").click(function () {
            ticker.server.closeMarket();
        });

        $("#reset").click(function () {
            ticker.server.reset();
        });
    });
```

The server methods are not wired up to the buttons until after the connection is established, so that the code can't try to call the server methods before they are available.

Next steps

In this tutorial you've learned how to program a SignalR application that broadcasts messages from the server to all connected clients, both on a periodic basis and in response to notifications from any client. The pattern of using a multi-threaded singleton instance to maintain server state can also be also used in multi-player online game scenarios. For an example, see the ShootR game that is based on SignalR.

For tutorials that show peer-to-peer communication scenarios, see Getting Started with SignalR and Real-Time Updating with SignalR.

ASP.NET SignalR Hubs API Guide - Server (SignalR 1.x)

2/20/2020 • 29 minutes to read • Edit Online

by Patrick Fletcher, Tom Dykstra

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document provides an introduction to programming the server side of the ASP.NET SignalR Hubs API for SignalR version 1.1, with code samples demonstrating common options.

The SignalR Hubs API enables you to make remote procedure calls (RPCs) from a server to connected clients and from clients to the server. In server code, you define methods that can be called by clients, and you call methods that run on the client. In client code, you define methods that can be called from the server, and you call methods that run on the server. SignalR takes care of all of the client-to-server plumbing for you.

SignalR also offers a lower-level API called Persistent Connections. For an introduction to SignalR, Hubs, and Persistent Connections, or for a tutorial that shows how to build a complete SignalR application, see SignalR - Getting Started.

Overview

This document contains the following sections:

- How to register the SignalR route and configure SignalR options
  - The /signalr URL
  - Configuring SignalR options
- How to create and use Hub classes
  - Hub object lifetime
  - Camel-casing of Hub names in JavaScript clients
  - Multiple Hubs
- How to define methods in the Hub class that clients can call
  - Camel-casing of method names in JavaScript clients
  - When to execute asynchronously
  - Defining overloads
- How to call client methods from the Hub class
  - Selecting which clients will receive the RPC
  - No compile-time validation for method names
  - Case-insensitive method name matching
  - Asynchronous execution
- How to manage group membership from the Hub class
  - Asynchronous execution of Add and Remove methods

- Group membership persistence
- Single-user groups
- How to handle connection lifetime events in the Hub class
  - When OnConnected, OnDisconnected, and OnReconnected are called
  - Caller state not populated
- How to get information about the client from the Context property
- How to pass state between clients and the Hub class
- How to handle errors in the Hub class
- How to call client methods and manage groups from outside the Hub class
  - Calling client methods
  - Managing group membership
- How to enable tracing
- How to customize the Hubs pipeline

For documentation on how to program clients, see the following resources:

- SignalR Hubs API Guide - JavaScript Client
- SignalR Hubs API Guide - .NET Client

Links to API Reference topics are to the .NET 4.5 version of the API. If you're using .NET 4, see the .NET 4 version of the API topics.

How to register the SignalR route and configure SignalR options

To define the route that clients will use to connect to your Hub, call the MapHubs method when the application starts. `MapHubs` is an extension method for the `System.Web.Routing.RouteCollection` class. The following example shows how to define the SignalR Hubs route in the *Global.asax* file.

```
using System.Web.Routing;
```

```
public class Global : System.Web.HttpApplication
{
    protected void Application_Start(object sender, EventArgs e)
    {
        RouteTable.Routes.MapHubs();
    }
}
```

If you are adding SignalR functionality to an ASP.NET MVC application, make sure that the SignalR route is added before the other routes. For more information, see Tutorial: Getting Started with SignalR and MVC 4.

The /signalr URL

By default, the route URL which clients will use to connect to your Hub is "/signalr". (Don't confuse this URL with the "/signalr/hubs" URL, which is for the automatically generated JavaScript file. For more information about the generated proxy, see SignalR Hubs API Guide - JavaScript Client - The generated proxy and what it does for you.)

There might be extraordinary circumstances that make this base URL not usable for SignalR; for example, you have a folder in your project named *signalr* and you don't want to change the name. In that case, you can change the base URL, as shown in the following examples (replace "/signalr" in the sample code with your desired URL).

Server code that specifies the URL

```
RouteTable.Routes.MapHubs("/signalr", new HubConfiguration());
```

JavaScript client code that specifies the URL (with the generated proxy)

```
$.connection.hub.url = "/signalr"
$.connection.hub.start().done(init);
```

JavaScript client code that specifies the URL (without the generated proxy)

```
var connection = $.hubConnection("/signalr", { useDefaultPath: false });
```

.NET client code that specifies the URL

```
var hubConnection = new HubConnection("http://contoso.com/signalr", useDefaultUrl: false);
```

Configuring SignalR Options

Overloads of the `MapHubs` method enable you to specify a custom URL, a custom dependency resolver, and the following options:

- Enable cross-domain calls from browser clients.

  Typically if the browser loads a page from `http://contoso.com`, the SignalR connection is in the same domain, at `http://contoso.com/signalr`. If the page from `http://contoso.com` makes a connection to `http://fabrikam.com/signalr`, that is a cross-domain connection. For security reasons, cross-domain connections are disabled by default. For more information, see ASP.NET SignalR Hubs API Guide - JavaScript Client - How to establish a cross-domain connection.

- Enable detailed error messages.

  When errors occur, the default behavior of SignalR is to send to clients a notification message without details about what happened. Sending detailed error information to clients is not recommended in production, because malicious users might be able to use the information in attacks against your application. For troubleshooting, you can use this option to temporarily enable more informative error reporting.

- Disable automatically generated JavaScript proxy files.

  By default, a JavaScript file with proxies for your Hub classes is generated in response to the URL "/signalr/hubs". If you don't want to use the JavaScript proxies, or if you want to generate this file manually and refer to a physical file in your clients, you can use this option to disable proxy generation. For more information, see SignalR Hubs API Guide - JavaScript Client - How to create a physical file for the SignalR generated proxy.

The following example shows how to specify the SignalR connection URL and these options in a call to the `MapHubs` method. To specify a custom URL, replace "/signalr" in the example with the URL that you want to use.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableCrossDomain = true;
hubConfiguration.EnableDetailedErrors = true;
hubConfiguration.EnableJavaScriptProxies = false;
RouteTable.Routes.MapHubs("/signalr", hubConfiguration);
```

How to create and use Hub classes

To create a Hub, create a class that derives from Microsoft.Aspnet.Signalr.Hub. The following example shows a simple Hub class for a chat application.

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addNewMessageToPage(name, message);
    }
}
```

In this example, a connected client can call the `NewContosoChatMessage` method, and when it does, the data received is broadcasted to all connected clients.

Hub object lifetime

You don't instantiate the Hub class or call its methods from your own code on the server; all that is done for you by the SignalR Hubs pipeline. SignalR creates a new instance of your Hub class each time it needs to handle a Hub operation such as when a client connects, disconnects, or makes a method call to the server.

Because instances of the Hub class are transient, you can't use them to maintain state from one method call to the next. Each time the server receives a method call from a client, a new instance of your Hub class processes the message. To maintain state through multiple connections and method calls, use some other method such as a database, or a static variable on the Hub class, or a different class that does not derive from `Hub`. If you persist data in memory, using a method such as a static variable on the Hub class, the data will be lost when the app domain recycles.

If you want to send messages to clients from your own code that runs outside the Hub class, you can't do it by instantiating a Hub class instance, but you can do it by getting a reference to the SignalR context object for your Hub class. For more information, see How to call client methods and manage groups from outside the Hub class later in this topic.

Camel-casing of Hub names in JavaScript clients

By default, JavaScript clients refer to Hubs by using a camel-cased version of the class name. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions. The previous example would be referred to as `contosoChatHub` in JavaScript code.

Server

```
public class ContosoChatHub : Hub
```

JavaScript client using generated proxy

```
var contosoChatHubProxy = $.connection.contosoChatHub;
```

If you want to specify a different name for clients to use, add the `HubName` attribute. When you use a `HubName` attribute, there is no name change to camel case on JavaScript clients.

Server

```
[HubName("PascalCaseContosoChatHub")]
public class ContosoChatHub : Hub
```

JavaScript client using generated proxy

```
var contosoChatHubProxy = $.connection.PascalCaseContosoChatHub;
```

Multiple Hubs

You can define multiple Hub classes in an application. When you do that, the connection is shared but groups are separate:

- All clients will use the same URL to establish a SignalR connection with your service ("/signalr" or your custom URL if you specified one), and that connection is used for all Hubs defined by the service.

  There is no performance difference for multiple Hubs compared to defining all Hub functionality in a single class.

- All Hubs get the same HTTP request information.

  Since all Hubs share the same connection, the only HTTP request information that the server gets is what comes in the original HTTP request that establishes the SignalR connection. If you use the connection request to pass information from the client to the server by specifying a query string, you can't provide different query strings to different Hubs. All Hubs will receive the same information.

- The generated JavaScript proxies file will contain proxies for all Hubs in one file.

  For information about JavaScript proxies, see SignalR Hubs API Guide - JavaScript Client - The generated proxy and what it does for you.

- Groups are defined within Hubs.

  In SignalR you can define named groups to broadcast to subsets of connected clients. Groups are maintained separately for each Hub. For example, a group named "Administrators" would include one set of clients for your `ContosoChatHub` class, and the same group name would refer to a different set of clients for your `StockTickerHub` class.

How to define methods in the Hub class that clients can call

To expose a method on the Hub that you want to be callable from the client, declare a public method, as shown in the following examples.

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addNewMessageToPage(name, message);
    }
}
```

```
public class StockTickerHub : Hub
{
    public IEnumerable<Stock> GetAllStocks()
    {
        return _stockTicker.GetAllStocks();
    }
}
```

You can specify a return type and parameters, including complex types and arrays, as you would in any C# method. Any data that you receive in parameters or return to the caller is communicated between the client and the server by using JSON, and SignalR handles the binding of complex objects and arrays of objects automatically.

Camel-casing of method names in JavaScript clients

By default, JavaScript clients refer to Hub methods by using a camel-cased version of the method name. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions.

Server

```
public void NewContosoChatMessage(string userName, string message)
```

JavaScript client using generated proxy

```
contosoChatHubProxy.server.newContosoChatMessage($(userName, message);
```

If you want to specify a different name for clients to use, add the `HubMethodName` attribute.

Server

```
[HubMethodName("PascalCaseNewContosoChatMessage")]
public void NewContosoChatMessage(string userName, string message)
```

JavaScript client using generated proxy

```
contosoChatHubProxy.server.PascalCaseNewContosoChatMessage(userName, message);
```

When to execute asynchronously

If the method will be long-running or has to do work that would involve waiting, such as a database lookup or a web service call, make the Hub method asynchronous by returning a Task (in place of `void` return) or Task<T> object (in place of `T` return type). When you return a `Task` object from the method, SignalR waits for the `Task` to complete, and then it sends the unwrapped result back to the client, so there is no difference in how you code the method call in the client.

Making a Hub method asynchronous avoids blocking the connection when it uses the WebSocket transport. When a Hub method executes synchronously and the transport is WebSocket, subsequent invocations of methods on the Hub from the same client are blocked until the Hub method completes.

The following example shows the same method coded to run synchronously or asynchronously, followed by JavaScript client code that works for calling either version.

Synchronous

```
public IEnumerable<Stock> GetAllStocks()
{
    // Returns data from memory.
    return _stockTicker.GetAllStocks();
}
```

Asynchronous - ASP.NET 4.5

```
public async Task<IEnumerable<Stock>> GetAllStocks()
{
    // Returns data from a web service.
    var uri = Util.getServiceUri("Stocks");
    using (HttpClient httpClient = new HttpClient())
    {
        var response = await httpClient.GetAsync(uri);
        return (await response.Content.ReadAsAsync<IEnumerable<Stock>>());
    }
}
```

JavaScript client using generated proxy

```
stockTickerHubProxy.server.getAllStocks().done(function (stocks) {
    $.each(stocks, function () {
        alert(this.Symbol + ' ' + this.Price);
    });
});
```

For more information about how to use asynchronous methods in ASP.NET 4.5, see Using Asynchronous Methods in ASP.NET MVC 4.

Defining Overloads

If you want to define overloads for a method, the number of parameters in each overload must be different. If you differentiate an overload just by specifying different parameter types, your Hub class will compile but the SignalR service will throw an exception at run time when clients try to call one of the overloads.

How to call client methods from the Hub class

To call client methods from the server, use the `Clients` property in a method in your Hub class. The following example shows server code that calls `addNewMessageToPage` on all connected clients, and client code that defines the method in a JavaScript client.

Server

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addNewMessageToPage(name, message);
    }
}
```

JavaScript client using generated proxy

```
contosoChatHubProxy.client.addNewMessageToPage = function (name, message) {
    // Add the message to the page.
    $('#discussion').append('<li><strong>' + htmlEncode(name)
        + '</strong>: ' + htmlEncode(message) + '<li>');
};
```

You can't get a return value from a client method; syntax such as `int x = Clients.All.add(1,1)` does not work.

You can specify complex types and arrays for the parameters. The following example passes a complex type to the client in a method parameter.

Server code that calls a client method using a complex object

```
public void SendMessage(string name, string message)
{
    Clients.All.addContosoChatMessageToPage(new ContosoChatMessage() { UserName = name, Message = message });
}
```

Server code that defines the complex object

```
public class ContosoChatMessage
{
    public string UserName { get; set; }
    public string Message { get; set; }
}
```

JavaScript client using generated proxy

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addMessageToPage = function (message) {
    console.log(message.UserName + ' ' + message.Message);
});
```

Selecting which clients will receive the RPC

The Clients property returns a HubConnectionContext object that provides several options for specifying which clients will receive the RPC:

- All connected clients.

  ```
  Clients.All.addContosoChatMessageToPage(name, message);
  ```

- Only the calling client.

  ```
  Clients.Caller.addContosoChatMessageToPage(name, message);
  ```

- All clients except the calling client.

  ```
  Clients.Others.addContosoChatMessageToPage(name, message);
  ```

- A specific client identified by connection ID.

  ```
  Clients.Client(Context.ConnectionId).addContosoChatMessageToPage(name, message);
  ```

  This example calls `addContosoChatMessageToPage` on the calling client and has the same effect as using `Clients.Caller`.

- All connected clients except the specified clients, identified by connection ID.

  ```
  Clients.AllExcept(connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
  ```

- All connected clients in a specified group.

  ```
  Clients.Group(groupName).addContosoChatMessageToPage(name, message);
  ```

- All connected clients in a specified group except the specified clients, identified by connection ID.

```
Clients.Group(groupName, connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
```

- All connected clients in a specified group except the calling client.

```
Clients.OthersInGroup(groupName).addContosoChatMessageToPage(name, message);
```

No compile-time validation for method names

The method name that you specify is interpreted as a dynamic object, which means there is no IntelliSense or compile-time validation for it. The expression is evaluated at run time. When the method call executes, SignalR sends the method name and the parameter values to the client, and if the client has a method that matches the name, that method is called and the parameter values are passed to it. If no matching method is found on the client, no error is raised. For information about the format of the data that SignalR transmits to the client behind the scenes when you call a client method, see Introduction to SignalR.

Case-insensitive method name matching

Method name matching is case-insensitive. For example, `Clients.All.addContosoChatMessageToPage` on the server will execute `AddContosoChatMessageToPage`, `addcontosochatmessagetopage`, or `addContosoChatMessageToPage` on the client.

Asynchronous execution

The method that you call executes asynchronously. Any code that comes after a method call to a client will execute immediately without waiting for SignalR to finish transmitting data to clients unless you specify that the subsequent lines of code should wait for method completion. The following code examples show how to execute two client methods sequentially, one using code that works in .NET 4.5, and one using code that works in .NET 4.

.NET 4.5 example

```
async public Task NewContosoChatMessage(string name, string message)
{
    await Clients.Others.addContosoChatMessageToPage(data);
    Clients.Caller.notifyMessageSent();
}
```

.NET 4 example

```
public void NewContosoChatMessage(string name, string message)
{
    (Clients.Others.addContosoChatMessageToPage(data) as Task).ContinueWith(antecedent =>
        Clients.Caller.notifyMessageSent());
}
```

If you use `await` or `ContinueWith` to wait until a client method finishes before the next line of code executes, that does not mean that clients will actually receive the message before the next line of code executes. "Completion" of a client method call only means that SignalR has done everything necessary to send the message. If you need verification that clients received the message, you have to program that mechanism yourself. For example, you could code a `MessageReceived` method on the Hub, and in the `addContosoChatMessageToPage` method on the client you could call `MessageReceived` after you do whatever work you need to do on the client. In `MessageReceived` in the Hub you can do whatever work depends on actual client reception and processing of the original method call.

How to use a string variable as the method name

If you want to invoke a client method by using a string variable as the method name, cast `Clients.All` (or

`Clients.Others`, `Clients.Caller`, etc.) to `IClientProxy` and then call Invoke(methodName, args...).

```
public void NewContosoChatMessage(string name, string message)
{
    string methodToCall = "addContosoChatMessageToPage";
    IClientProxy proxy = Clients.All;
    proxy.Invoke(methodToCall, name, message);
}
```

How to manage group membership from the Hub class

Groups in SignalR provide a method for broadcasting messages to specified subsets of connected clients. A group can have any number of clients, and a client can be a member of any number of groups.

To manage group membership, use the Add and Remove methods provided by the `Groups` property of the Hub class. The following example shows the `Groups.Add` and `Groups.Remove` methods used in Hub methods that are called by client code, followed by JavaScript client code that calls them.

Server

```
public class ContosoChatHub : Hub
{
    public Task JoinGroup(string groupName)
    {
        return Groups.Add(Context.ConnectionId, groupName);
    }

    public Task LeaveGroup(string groupName)
    {
        return Groups.Remove(Context.ConnectionId, groupName);
    }
}
```

JavaScript client using generated proxy

```
contosoChatHubProxy.server.joinGroup(groupName);
```

```
contosoChatHubProxy.server.leaveGroup(groupName);
```

You don't have to explicitly create groups. In effect a group is automatically created the first time you specify its name in a call to `Groups.Add`, and it is deleted when you remove the last connection from membership in it.

There is no API for getting a group membership list or a list of groups. SignalR sends messages to clients and groups based on a pub/sub model, and the server does not maintain lists of groups or group memberships. This helps maximize scalability, because whenever you add a node to a web farm, any state that SignalR maintains has to be propagated to the new node.

Asynchronous execution of Add and Remove methods

The `Groups.Add` and `Groups.Remove` methods execute asynchronously. If you want to add a client to a group and immediately send a message to the client by using the group, you have to make sure that the `Groups.Add` method finishes first. The following code examples show how to do that, one by using code that works in .NET 4.5, and one by using code that works in .NET 4

.NET 4.5 example

```
async public Task JoinGroup(string groupName)
{
    await Groups.Add(Context.ConnectionId, groupName);
    Clients.Group(groupname).addContosoChatMessageToPage(Context.ConnectionId + " added to group");
}
```

.NET 4 example

```
public void JoinGroup(string groupName)
{
    (Groups.Add(Context.ConnectionId, groupName) as Task).ContinueWith(antecedent =>
        Clients.Group(groupName).addContosoChatMessageToPage(Context.ConnectionId + " added to group"));
}
```

Group membership persistence

SignalR tracks connections, not users, so if you want a user to be in the same group every time the user establishes a connection, you have to call `Groups.Add` every time the user establishes a new connection.

After a temporary loss of connectivity, sometimes SignalR can restore the connection automatically. In that case, SignalR is restoring the same connection, not establishing a new connection, and so the client's group membership is automatically restored. This is possible even when the temporary break is the result of a server reboot or failure, because connection state for each client, including group memberships, is round-tripped to the client. If a server goes down and is replaced by a new server before the connection times out, a client can reconnect automatically to the new server and re-enroll in groups it is a member of.

When a connection can't be restored automatically after a loss of connectivity, or when the connection times out, or when the client disconnects (for example, when a browser navigates to a new page), group memberships are lost. The next time the user connects will be a new connection. To maintain group memberships when the same user establishes a new connection, your application has to track the associations between users and groups, and restore group memberships each time a user establishes a new connection.

For more information about connections and reconnections, see How to handle connection lifetime events in the Hub class later in this topic.

Single-user groups

Applications that use SignalR typically have to keep track of the associations between users and connections in order to know which user has sent a message and which user(s) should be receiving a message. Groups are used in one of the two commonly used patterns for doing that.

- Single-user groups.

  You can specify the user name as the group name, and add the current connection ID to the group every time the user connects or reconnects. To send messages to the user you send to the group. A disadvantage of this method is that the group doesn't provide you with a way to find out if the user is online or offline.

- Track associations between user names and connection IDs.

  You can store an association between each user name and one or more connection IDs in a dictionary or database, and update the stored data each time the user connects or disconnects. To send messages to the user you specify the connection IDs. A disadvantage of this method is that it takes more memory.

How to handle connection lifetime events in the Hub class

Typical reasons for handling connection lifetime events are to keep track of whether a user is connected or not, and to keep track of the association between user names and connection IDs. To run your own code when clients connect or disconnect, override the `OnConnected`, `OnDisconnected`, and `OnReconnected` virtual methods of the Hub

class, as shown in the following example.

```
public class ContosoChatHub : Hub
{
    public override Task OnConnected()
    {
        // Add your own code here.
        // For example: in a chat application, record the association between
        // the current connection ID and user name, and mark the user as online.
        // After the code in this method completes, the client is informed that
        // the connection is established; for example, in a JavaScript client,
        // the start().done callback is executed.
        return base.OnConnected();
    }

    public override Task OnDisconnected()
    {
        // Add your own code here.
        // For example: in a chat application, mark the user as offline,
        // delete the association between the current connection id and user name.
        return base.OnDisconnected();
    }

    public override Task OnReconnected()
    {
        // Add your own code here.
        // For example: in a chat application, you might have marked the
        // user as offline after a period of inactivity; in that case
        // mark the user as online again.
        return base.OnReconnected();
    }
}
```

When OnConnected, OnDisconnected, and OnReconnected are called

Each time a browser navigates to a new page, a new connection has to be established, which means SignalR will execute the `OnDisconnected` method followed by the `OnConnected` method. SignalR always creates a new connection ID when a new connection is established.

The `OnReconnected` method is called when there has been a temporary break in connectivity that SignalR can automatically recover from, such as when a cable is temporarily disconnected and reconnected before the connection times out. The `OnDisconnected` method is called when the client is disconnected and SignalR can't automatically reconnect, such as when a browser navigates to a new page. Therefore, a possible sequence of events for a given client is `OnConnected`, `OnReconnected`, `OnDisconnected`; or `OnConnected`, `OnDisconnected`. You won't see the sequence `OnConnected`, `OnDisconnected`, `OnReconnected` for a given connection.

The `OnDisconnected` method doesn't get called in some scenarios, such as when a server goes down or the App Domain gets recycled. When another server comes on line or the App Domain completes its recycle, some clients may be able to reconnect and fire the `OnReconnected` event.

For more information, see Understanding and Handling Connection Lifetime Events in SignalR.

Caller state not populated

The connection lifetime event handler methods are called from the server, which means that any state that you put in the `state` object on the client will not be populated in the `Caller` property on the server. For information about the `state` object and the `Caller` property, see How to pass state between clients and the Hub class later in this topic.

How to get information about the client from the Context property

To get information about the client, use the `Context` property of the Hub class. The `Context` property returns a

HubCallerContext object which provides access to the following information:

- The connection ID of the calling client.

  ```
  string connectionID = Context.ConnectionId;
  ```

  The connection ID is a GUID that is assigned by SignalR (you can't specify the value in your own code). There is one connection ID for each connection, and the same connection ID is used by all Hubs if you have multiple Hubs in your application.

- HTTP header data.

  ```
  System.Collections.Specialized.NameValueCollection headers = Context.Request.Headers;
  ```

  You can also get HTTP headers from `Context.Headers`. The reason for multiple references to the same thing is that `Context.Headers` was created first, the `Context.Request` property was added later, and `Context.Headers` was retained for backward compatibility.

- Query string data.

  ```
  System.Collections.Specialized.NameValueCollection queryString = Context.Request.QueryString;
  string parameterValue = queryString["parametername"]
  ```

  You can also get query string data from `Context.QueryString`.

  The query string that you get in this property is the one that was used with the HTTP request that established the SignalR connection. You can add query string parameters in the client by configuring the connection, which is a convenient way to pass data about the client from the client to the server. The following example shows one way to add a query string in a JavaScript client when you use the generated proxy.

  ```
  $.connection.hub.qs = { "version" : "1.0" };
  ```

  For more information about setting query string parameters, see the API guides for the JavaScript and .NET clients.

  You can find the transport method used for the connection in the query string data, along with some other values used internally by SignalR:

  ```
  string transportMethod = queryString["transport"];
  ```

  The value of `transportMethod` will be "webSockets", "serverSentEvents", "foreverFrame" or "longPolling". Note that if you check this value in the `OnConnected` event handler method, in some scenarios you might initially get a transport value that is not the final negotiated transport method for the connection. In that case the method will throw an exception and will be called again later when the final transport method is established.

- Cookies.

  ```
  System.Collections.Generic.IDictionary<string, Cookie> cookies = Context.Request.Cookies;
  ```

  You can also get cookies from `Context.RequestCookies`.

- User information.

```
System.Security.Principal.IPrincipal user = Context.User;
```

- The HttpContext object for the request :

```
System.Web.HttpContextBase httpContext = Context.Request.GetHttpContext();
```

  Use this method instead of getting `HttpContext.Current` to get the `HttpContext` object for the SignalR connection.

How to pass state between clients and the Hub class

The client proxy provides a `state` object in which you can store data that you want to be transmitted to the server with each method call. On the server you can access this data in the `Clients.Caller` property in Hub methods that are called by clients. The `Clients.Caller` property is not populated for the connection lifetime event handler methods `OnConnected`, `OnDisconnected`, and `OnReconnected`.

Creating or updating data in the `state` object and the `Clients.Caller` property works in both directions. You can update values in the server and they are passed back to the client.

The following example shows JavaScript client code that stores state for transmission to the server with every method call.

```
contosoChatHubProxy.state.userName = "Fadi Fakhouri";
contosoChatHubProxy.state.computerName = "fadivm1";
```

The following example shows the equivalent code in a .NET client.

```
contosoChatHubProxy["userName"] = "Fadi Fakhouri";
chatHubProxy["computerName"] = "fadivm1";
```

In your Hub class, you can access this data in the `Clients.Caller` property. The following example shows code that retrieves the state referred to in the previous example.

```
public void NewContosoChatMessage(string data)
{
    string userName = Clients.Caller.userName;
    string computerName = Clients.Caller.computerName;
    Clients.Others.addContosoChatMessageToPage(message, userName, computerName);
}
```

> **NOTE**
> This mechanism for persisting state is not intended for large amounts of data, since everything you put in the `state` or `Clients.Caller` property is round-tripped with every method invocation. It's useful for smaller items such as user names or counters.

How to handle errors in the Hub class

To handle errors that occur in your Hub class methods, use one or both of the following methods:

- Wrap your method code in try-catch blocks and log the exception object. For debugging purposes you can send the exception to the client, but for security reasons sending detailed information to clients in production is not recommended.
- Create a Hubs pipeline module that handles the OnIncomingError method. The following example shows a pipeline module that logs errors, followed by code in Global.asax that injects the module into the Hubs pipeline.

```
public class ErrorHandlingPipelineModule : HubPipelineModule
{
    protected override void OnIncomingError(Exception ex, IHubIncomingInvokerContext context)
    {
        Debug.WriteLine("=> Exception " + ex.Message);
        if (ex.InnerException != null)
        {
            Debug.WriteLine("=> Inner Exception " + ex.InnerException.Message);
        }
        base.OnIncomingError(ex, context);
    }
}
```

```
protected void Application_Start(object sender, EventArgs e)
{
    GlobalHost.HubPipeline.AddModule(new ErrorHandlingPipelineModule());
    RouteTable.Routes.MapHubs();
}
```

For more information about Hub pipeline modules, see How to customize the Hubs pipeline later in this topic.

How to enable tracing

To enable server-side tracing, add a system.diagnostics element to your Web.config file, as shown in this example:

```
<configuration>
  <configSections>
    <!-- For more information on Entity Framework configuration, visit https://go.microsoft.com/fwlink/?
LinkID=237468 -->
    <section name="entityFramework" type="System.Data.Entity.Internal.ConfigFile.EntityFrameworkSection,
EntityFramework, Version=5.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089" requirePermission="false"
/>
  </configSections>
  <connectionStrings>
    <add name="SignalRSamples" connectionString="Data Source=(local);Initial Catalog=SignalRSamples;Integrated
Security=SSPI;Asynchronous Processing=True;" />
    <add name="SignalRSamplesWithMARS" connectionString="Data Source=(local);Initial
Catalog=SignalRSamples;Integrated Security=SSPI;Asynchronous Processing=True;MultipleActiveResultSets=true;"
/>
  </connectionStrings>
  <system.web>
    <compilation debug="true" targetFramework="4.5" />
    <httpRuntime targetFramework="4.5" />
  </system.web>
  <system.webServer>
    <modules runAllManagedModulesForAllRequests="true" />
  </system.webServer>
  <system.diagnostics>
    <sources>
      <source name="SignalR.SqlMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
```

```
      <source name="SignalR.ServiceBusMessageBus">
        <listeners>
            <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.ScaleoutMessageBus">
        <listeners>
            <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.Transports.WebSocketTransport">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.ServerSentEventsTransport">
          <listeners>
              <add name="SignalR-Transports" />
          </listeners>
      </source>
      <source name="SignalR.Transports.ForeverFrameTransport">
          <listeners>
              <add name="SignalR-Transports" />
          </listeners>
      </source>
      <source name="SignalR.Transports.LongPollingTransport">
        <listeners>
            <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.TransportHeartBeat">
        <listeners>
            <add name="SignalR-Transports" />
        </listeners>
      </source>
    </sources>
    <switches>
      <add name="SignalRSwitch" value="Verbose" />
    </switches>
    <sharedListeners>
      <add name="SignalR-Transports"
           type="System.Diagnostics.TextWriterTraceListener"
           initializeData="transports.log.txt" />
        <add name="SignalR-Bus"
           type="System.Diagnostics.TextWriterTraceListener"
           initializeData="bus.log.txt" />
    </sharedListeners>
    <trace autoflush="true" />
  </system.diagnostics>
  <entityFramework>
    <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFactory,
EntityFramework">
      <parameters>
        <parameter value="v11.0" />
      </parameters>
    </defaultConnectionFactory>
  </entityFramework>
</configuration>
```

When you run the application in Visual Studio, you can view the logs in the **Output** window.

How to call client methods and manage groups from outside the Hub class

To call client methods from a different class than your Hub class, get a reference to the SignalR context object for

the Hub and use that to call methods on the client or manage groups.

The following sample `StockTicker` class gets the context object, stores it in an instance of the class, stores the class instance in a static property, and uses the context from the singleton class instance to call the `updateStockPrice` method on clients that are connected to a Hub named `StockTickerHub`.

```
// For the complete example, go to
// http://www.asp.net/signalr/overview/signalr-1x/getting-started/tutorial-server-broadcast-with-aspnet-
signalr
// This sample only shows code related to getting and using the SignalR context.
public class StockTicker
{
    // Singleton instance
    private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(
        () => new StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>()));

    private IHubContext _context;

    private StockTicker(IHubContext context)
    {
        _context = context;
    }

    // This method is invoked by a Timer object.
    private void UpdateStockPrices(object state)
    {
        foreach (var stock in _stocks.Values)
        {
            if (TryUpdateStockPrice(stock))
            {
                _context.Clients.All.updateStockPrice(stock);
            }
        }
    }
```

If you need to use the context multiple-times in a long-lived object, get the reference once and save it rather than getting it again each time. Getting the context once ensures that SignalR sends messages to clients in the same sequence in which your Hub methods make client method invocations. For a tutorial that shows how to use the SignalR context for a Hub, see Server Broadcast with ASP.NET SignalR.

Calling client methods

You can specify which clients will receive the RPC, but you have fewer options than when you call from a Hub class. The reason for this is that the context is not associated with a particular call from a client, so any methods that require knowledge of the current connection ID, such as `Clients.Others`, or `Clients.Caller`, or `Clients.OthersInGroup`, are not available. The following options are available:

- All connected clients.

  ```
  context.Clients.All.addContosoChatMessageToPage(name, message);
  ```

- A specific client identified by connection ID.

  ```
  context.Clients.Client(connectionID).addContosoChatMessageToPage(name, message);
  ```

- All connected clients except the specified clients, identified by connection ID.

  ```
  context.Clients.AllExcept(connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
  ```

- All connected clients in a specified group.

```
context.Clients.Group(groupName).addContosoChatMessageToPage(name, message);
```

- All connected clients in a specified group except specified clients, identified by connection ID.

```
Clients.Group(groupName, connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
```

If you are calling into your non-Hub class from methods in your Hub class, you can pass in the current connection ID and use that with `Clients.Client`, `Clients.AllExcept`, or `Clients.Group` to simulate `Clients.Caller`, `Clients.Others`, or `Clients.OthersInGroup`. In the following example, the `MoveShapeHub` class passes the connection ID to the `Broadcaster` class so that the `Broadcaster` class can simulate `Clients.Others`.

```
// For the complete example, see
// http://www.asp.net/signalr/overview/getting-started/tutorial-high-frequency-realtime-with-signalr
// This sample only shows code that passes connection ID to the non-Hub class,
// in order to simulate Clients.Others.
public class MoveShapeHub : Hub
{
    // Code not shown puts a singleton instance of Broadcaster in this variable.
    private Broadcaster _broadcaster;

    public void UpdateModel(ShapeModel clientModel)
    {
        clientModel.LastUpdatedBy = Context.ConnectionId;
        // Update the shape model within our broadcaster
        _broadcaster.UpdateShape(clientModel);
    }
}

public class Broadcaster
{
    public Broadcaster()
    {
        _hubContext = GlobalHost.ConnectionManager.GetHubContext<MoveShapeHub>();
    }

    public void UpdateShape(ShapeModel clientModel)
    {
        _model = clientModel;
        _modelUpdated = true;
    }

    // Called by a Timer object.
    public void BroadcastShape(object state)
    {
        if (_modelUpdated)
        {
            _hubContext.Clients.AllExcept(_model.LastUpdatedBy).updateShape(_model);
            _modelUpdated = false;
        }
    }
}
```

Managing group membership

For managing groups you have the same options as you do in a Hub class.

- Add a client to a group

```
context.Groups.Add(connectionID, groupName);
```

- Remove a client from a group

```
context.Groups.Remove(connectionID, groupName);
```

How to customize the Hubs pipeline

SignalR enables you to inject your own code into the Hub pipeline. The following example shows a custom Hub pipeline module that logs each incoming method call received from the client and outgoing method call invoked on the client:

```
public class LoggingPipelineModule : HubPipelineModule
{
    protected override bool OnBeforeIncoming(IHubIncomingInvokerContext context)
    {
        Debug.WriteLine("=> Invoking " + context.MethodDescriptor.Name + " on hub " +
context.MethodDescriptor.Hub.Name);
        return base.OnBeforeIncoming(context);
    }
    protected override bool OnBeforeOutgoing(IHubOutgoingInvokerContext context)
    {
        Debug.WriteLine("<= Invoking " + context.Invocation.Method + " on client hub " +
context.Invocation.Hub);
        return base.OnBeforeOutgoing(context);
    }
}
```

The following code in the *Global.asax* file registers the module to run in the Hub pipeline:

```
protected void Application_Start(object sender, EventArgs e)
{
    GlobalHost.HubPipeline.AddModule(new LoggingPipelineModule());
    RouteTable.Routes.MapHubs();
}
```

There are many different methods that you can override. For a complete list, see HubPipelineModule Methods.

SignalR 1.x Hubs API Guide - JavaScript Client

2/20/2020 • 21 minutes to read • Edit Online

by Patrick Fletcher, Tom Dykstra

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document provides an introduction to using the Hubs API for SignalR version 1.1 in JavaScript clients, such as browsers and Windows Store (WinJS) applications.

The SignalR Hubs API enables you to make remote procedure calls (RPCs) from a server to connected clients and from clients to the server. In server code, you define methods that can be called by clients, and you call methods that run on the client. In client code, you define methods that can be called from the server, and you call methods that run on the server. SignalR takes care of all of the client-to-server plumbing for you.

SignalR also offers a lower-level API called Persistent Connections. For an introduction to SignalR, Hubs, and Persistent Connections, or for a tutorial that shows how to build a complete SignalR application, see SignalR - Getting Started.

Overview

This document contains the following sections:

- The generated proxy and what it does for you
  - When to use the generated proxy
- Client Setup
  - How to reference the dynamically generated proxy
  - How to create a physical file for the SignalR generated proxy
- How to establish a connection
  - $.connection.hub is the same object that $.hubConnection() creates
  - Asynchronous execution of the start method
- How to establish a cross-domain connection
- How to configure the connection
  - How to specify query string parameters
  - How to specify the transport method
- How to get a proxy for a Hub class
- How to define methods on the client that the server can call
- How to call server methods from the client
- How to handle connection lifetime events
- How to handle errors
- How to enable client-side logging

For documentation on how to program the server or .NET clients, see the following resources:

- SignalR Hubs API Guide - Server
- SignalR Hubs API Guide - .NET Client

Links to API Reference topics are to the .NET 4.5 version of the API. If you're using .NET 4, see the .NET 4 version of the API topics.

The generated proxy and what it does for you

You can program a JavaScript client to communicate with a SignalR service with or without a proxy that SignalR generates for you. What the proxy does for you is simplify the syntax of the code you use to connect, write methods that the server calls, and call methods on the server.

When you write code to call server methods, the generated proxy enables you to use syntax that looks as though you were executing a local function: you can write `serverMethod(arg1, arg2)` instead of `invoke('serverMethod', arg1, arg2)`. The generated proxy syntax also enables an immediate and intelligible client-side error if you mistype a server method name. And if you manually create the file that defines the proxies, you can also get IntelliSense support for writing code that calls server methods.

For example, suppose you have the following Hub class on the server:

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addContosoChatMessageToPage(name, message);
    }
}
```

The following code examples show what JavaScript code looks like for invoking the `NewContosoChatMessage` method on the server and receiving invocations of the `addContosoChatMessageToPage` method from the server.

With the generated proxy

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addContosoChatMessageToPage = function (name, message) {
    console.log(name + ' ' + message);
};
$.connection.hub.start().done(function () {
    // Wire up Send button to call NewContosoChatMessage on the server.
    $('#newContosoChatMessage').click(function () {
         contosoChatHubProxy.server.newContosoChatMessage($('#displayname').val(), $('#message').val());
         $('#message').val('').focus();
     });
});
```

Without the generated proxy

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
contosoChatHubProxy.on('addContosoChatMessageToPage', function(name, message) {
    console.log(name + ' ' + message);
});
connection.start().done(function() {
    // Wire up Send button to call NewContosoChatMessage on the server.
    $('#newContosoChatMessage').click(function () {
        contosoChatHubProxy.invoke('newContosoChatMessage', $('#displayname').val(), $('#message').val());
        $('#message').val('').focus();
                });
    });
```

When to use the generated proxy

If you want to register multiple event handlers for a client method that the server calls, you can't use the generated proxy. Otherwise, you can choose to use the generated proxy or not based on your coding preference. If you choose not to use it, you don't have to reference the "signalr/hubs" URL in a `script` element in your client code.

Client setup

A JavaScript client requires references to jQuery and the SignalR core JavaScript file. The jQuery version must be 1.6.4 or major later versions, such as 1.7.2, 1.8.2, or 1.9.1. If you decide to use the generated proxy, you also need a reference to the SignalR generated proxy JavaScript file. The following example shows what the references might look like in an HTML page that uses the generated proxy.

```
<script src="Scripts/jquery-1.6.4.min.js"></script>
<script src="Scripts/jquery.signalR-1.0.1.min.js"></script>
<script src="signalr/hubs"></script>
```

These references must be included in this order: jQuery first, SignalR core after that, and SignalR proxies last.

How to reference the dynamically generated proxy

In the preceding example, the reference to the SignalR generated proxy is to dynamically generated JavaScript code, not to a physical file. SignalR creates the JavaScript code for the proxy on the fly and serves it to the client in response to the "/signalr/hubs" URL. If you specified a different base URL for SignalR connections on the server in your `MapHubs` method, the URL for the dynamically generated proxy file is your custom URL with "/hubs" appended to it.

> **NOTE**
> For Windows 8 (Windows Store) JavaScript clients, use the physical proxy file instead of the dynamically generated one. For more information, see How to create a physical file for the SignalR generated proxy later in this topic.

In an ASP.NET MVC 4 Razor view, use the tilde to refer to the application root in your proxy file reference:

```
<script src="~/signalr/hubs"></script>
```

For more information about using SignalR in MVC 4, see Getting Started with SignalR and MVC 4.

In an ASP.NET MVC 3 Razor view, use `Url.Content` for your proxy file reference:

```
<script src="@Url.Content("~/signalr/hubs")"></script>
```

In an ASP.NET Web Forms application, use `ResolveClientUrl` for your proxies file reference or register it via the ScriptManager using an app root relative path (starting with a tilde):

```
<script src='<%: ResolveClientUrl("~/signalr/hubs") %>'></script>
```

As a general rule, use the same method for specifying the "/signalr/hubs" URL that you use for CSS or JavaScript files. If you specify a URL without using a tilde, in some scenarios your application will work correctly when you test in Visual Studio using IIS Express but will fail with a 404 error when you deploy to full IIS. For more information, see **Resolving References to Root-Level Resources** in Web Servers in Visual Studio for ASP.NET Web Projects on the MSDN site.

When you run a web project in Visual Studio 2012 in debug mode, and if you use Internet Explorer as your browser, you can see the proxy file in **Solution Explorer** under **Script Documents**, as shown in the following illustration.

To see the contents of the file, double-click **hubs**. If you are not using Visual Studio 2012 and Internet Explorer, or if you are not in debug mode, you can also get the contents of the file by browsing to the "/signalR/hubs" URL. For example, if your site is running at `http://localhost:56699`, go to `http://localhost:56699/SignalR/hubs` in your browser.

How to create a physical file for the SignalR generated proxy

As an alternative to the dynamically generated proxy, you can create a physical file that has the proxy code and reference that file. You might want to do that for control over caching or bundling behavior, or to get IntelliSense when you are coding calls to server methods.

To create a proxy file, perform the following steps:

1. Install the Microsoft.AspNet.SignalR.Utils NuGet package.

2. Open a command prompt and browse to the *tools* folder that contains the SignalR.exe file. The tools folder is at the following location:

   ```
   [your solution folder]\packages\Microsoft.AspNet.SignalR.Utils.1.0.1\tools
   ```

3. Enter the following command:

   ```
   signalr ghp /path:[path to the .dll that contains your Hub class]
   ```

The path to your *.dll* is typically the *bin* folder in your project folder.

This command creates a file named *server.js* in the same folder as *signalr.exe*.

4. Put the *server.js* file in an appropriate folder in your project, rename it as appropriate for your application, and add a reference to it in place of the "signalr/hubs" reference.

How to establish a connection

Before you can establish a connection, you have to create a connection object, create a proxy, and register event handlers for methods that can be called from the server. When the proxy and event handlers are set up, establish the connection by calling the `start` method.

If you are using the generated proxy, you don't have to create the connection object in your own code because the generated proxy code does it for you.

Establish a connection (with the generated proxy)

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addContosoChatMessageToPage = function (name, message) {
    console.log(userName + ' ' + message);
};
$.connection.hub.start()
    .done(function(){ console.log('Now connected, connection ID=' + $.connection.hub.id); })
    .fail(function(){ console.log('Could not Connect!'); });
});
```

Establish a connection (without the generated proxy)

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
contosoChatHubProxy.on('addContosoChatMessageToPage', function(userName, message) {
    console.log(userName + ' ' + message);
});
connection.start()
    .done(function(){ console.log('Now connected, connection ID=' + connection.id); })
    .fail(function(){ console.log('Could not connect'); });
```

The sample code uses the default "/signalr" URL to connect to your SignalR service. For information about how to specify a different base URL, see ASP.NET SignalR Hubs API Guide - Server - The /signalr URL.

> **NOTE**
> Normally you register event handlers before calling the `start` method to establish the connection. If you want to register some event handlers after establishing the connection, you can do that, but you must register at least one of your event handler(s) before calling the `start` method. One reason for this is that there can be many Hubs in an application, but you wouldn't want to trigger the `OnConnected` event on every Hub if you are only going to use to one of them. When the connection is established, the presence of a client method on a Hub's proxy is what tells SignalR to trigger the `OnConnected` event. If you don't register any event handlers before calling the `start` method, you will be able to invoke methods on the Hub, but the Hub's `OnConnected` method won't be called and no client methods will be invoked from the server.

$.connection.hub is the same object that $.hubConnection() creates

As you can see from the examples, when you use the generated proxy, `$.connection.hub` refers to the connection object. This is the same object that you get by calling `$.hubConnection()` when you aren't using the generated proxy. The generated proxy code creates the connection for you by executing the following statement:

```
// This line is at the end of the generated proxy code.
signalR.hub = $.hubConnection("/signalr", { useDefaultPath: false });
```

When you're using the generated proxy, you can do anything with `$.connection.hub` that you can do with a connection object when you're not using the generated proxy.

Asynchronous execution of the start method

The `start` method executes asynchronously. It returns a jQuery Deferred object, which means that you can add callback functions by calling methods such as `pipe`, `done`, and `fail`. If you have code that you want to execute after the connection is established, such as a call to a server method, put that code in a callback function or call it from a callback function. The `.done` callback method is executed after the connection has been established, and after any code that you have in your `OnConnected` event handler method on the server finishes executing.

If you put the "Now connected" statement from the preceding example as the next line of code after the `start` method call (not in a `.done` callback), the `console.log` line will execute before the connection is established, as shown in the following example:

```
$.connection.hub.start();
console.log("Now connected, connection ID=" + $.connection.hub.id);
```

How to establish a cross-domain connection

Typically if the browser loads a page from `http://contoso.com`, the SignalR connection is in the same domain, at `http://contoso.com/signalr`. If the page from `http://contoso.com` makes a connection to `http://fabrikam.com/signalr`, that is a cross-domain connection. For security reasons, cross-domain connections are disabled by default. To establish a cross-domain connection, make sure that cross-domain connections are enabled on the server, and specify the connection URL when you create the connection object. SignalR will use the appropriate technology for cross-domain connections, such as JSONP or CORS.

On the server, enable cross-domain connections by selecting that option when you call the `MapHubs` method.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableCrossDomain = true;
RouteTable.Routes.MapHubs(hubConfiguration);
```

On the client, specify the URL when you create the connection object (without the generated proxy) or before you call the start method (with the generated proxy).

Client code that specifies a cross-domain connection (with the generated proxy)

```
$.connection.hub.url = 'http://fabrikam.com/signalr'
$.connection.hub.start().done(init);
```

Client code that specifies a cross-domain connection (without the generated proxy)

```
var connection = $.hubConnection('http://fabrikam.com/');
```

When you use the `$.hubConnection` constructor, you don't have to include `signalr` in the URL because it is added automatically (unless you specify `useDefaultUrl` as `false`).

You can create multiple connections to different endpoints.

```
var connection1 = $.hubConnection('http://contoso.com/');
var connection2 = $.hubConnection('http://fabrikam.com/');
```

NOTE

- Don't set `jQuery.support.cors` to true in your code.

  ```
  // Don't put the following line in your code.
  jQuery.support.cors = true;
  $.connection.hub.start();
  ```

  SignalR handles the use of JSONP or CORS. Setting `jQuery.support.cors` to true disables JSONP because it causes SignalR to assume the browser supports CORS.

- When you're connecting to a localhost URL, Internet Explorer 10 won't consider it a cross-domain connection, so the application will work locally with IE 10 even if you haven't enabled cross-domain connections on the server.
- For information about using cross-domain connections with Internet Explorer 9, see this StackOverflow thread.
- For information about using cross-domain connections with Chrome, see this StackOverflow thread.
- The sample code uses the default "/signalr" URL to connect to your SignalR service. For information about how to specify a different base URL, see ASP.NET SignalR Hubs API Guide - Server - The /signalr URL.

How to configure the connection

Before you establish a connection, you can specify query string parameters or specify the transport method.

How to specify query string parameters

If you want to send data to the server when the client connects, you can add query string parameters to the connection object. The following examples show how to set a query string parameter in client code.

Set a query string value before calling the start method (with the generated proxy)

```
$.connection.hub.qs = { 'version' : '1.0' };
```

Set a query string value before calling the start method (without the generated proxy)

```
var connection = $.hubConnection();
connection.qs = { 'version' : '1.0' };
```

The following example shows how to read a query string parameter in server code.

```
public class ContosoChatHub : Hub
{
    public override Task OnConnected()
    {
        var version = Context.QueryString['version'];
        if (version != '1.0')
        {
            Clients.Caller.notifyWrongVersion();
        }
        return base.OnConnected();
    }
}
```

How to specify the transport method

As part of the process of connecting, a SignalR client normally negotiates with the server to determine the best transport that is supported by both server and client. If you already know which transport you want to use, you can bypass this negotiation process by specifying the transport method when you call the `start` method.

Client code that specifies the transport method (with the generated proxy)

```
$.connection.hub.start( { transport: 'longPolling' });
```

Client code that specifies the transport method (without the generated proxy)

```
var connection = $.hubConnection();
connection.start({ transport: 'longPolling' });
```

As an alternative, you can specify multiple transport methods in the order in which you want SignalR to try them:

Client code that specifies a custom transport fallback scheme (with the generated proxy)

```
$.connection.hub.start( { transport: ['webSockets', 'longPolling'] });
```

Client code that specifies a custom transport fallback scheme (without the generated proxy)

```
var connection = $.hubConnection();
connection.start({ transport: ['webSockets', 'longPolling'] });
```

You can use the following values for specifying the transport method:

- "webSockets"
- "foreverFrame"
- "serverSentEvents"
- "longPolling"

The following examples show how to find out which transport method is being used by a connection.

Client code that displays the transport method used by a connection (with the generated proxy)

```
$.connection.hub.start().done(function () {
    console.log("Connected, transport = " + $.connection.hub.transport.name);
});
```

Client code that displays the transport method used by a connection (without the generated proxy)

```
var connection = $.hubConnection();
connection.hub.start().done(function () {
    console.log("Connected, transport = " + connection.transport.name);
});
```

For information about how to check the transport method in server code, see ASP.NET SignalR Hubs API Guide - Server - How to get information about the client from the Context property. For more information about transports and fallbacks, see Introduction to SignalR - Transports and Fallbacks.

How to get a proxy for a Hub class

Each connection object that you create encapsulates information about a connection to a SignalR service that contains one or more Hub classes. To communicate with a Hub class, you use a proxy object which you create yourself (if you're not using the generated proxy) or which is generated for you.

On the client the proxy name is a camel-cased version of the Hub class name. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions.

Hub class on server

```
public class ContosoChatHub : Hub
```

Get a reference to the generated client proxy for the Hub

```
var myHubProxy = $.connection.contosoChatHub
```

Create client proxy for the Hub class (without generated proxy)

```
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
```

If you decorate your Hub class with a `HubName` attribute, use the exact name without changing case.

Hub class on server with HubName attribute

```
[HubName("ContosoChatHub")]
public class ChatHub : Hub
```

Get a reference to the generated client proxy for the Hub

```
var contosoChatHubProxy = $.connection.ContosoChatHub
```

Create client proxy for the Hub class (without generated proxy)

```
var contosoChatHubProxy = connection.createHubProxy('ContosoChatHub');
```

How to define methods on the client that the server can call

To define a method that the server can call from a Hub, add an event handler to the Hub proxy by using the `client` property of the generated proxy, or call the `on` method if you aren't using the generated proxy. The parameters can be complex objects.

Add the event handler before you call the `start` method to establish the connection. (If you want to add event handlers after calling the `start` method, see the note in How to establish a connection earlier in this document, and use the syntax shown for defining a method without using the generated proxy.)

Method name matching is case-insensitive. For example, `Clients.All.addContosoChatMessageToPage` on the server will execute `AddContosoChatMessageToPage`, `addContosoChatMessageToPage`, or `addcontosochatmessagetopage` on the client.

Define method on client (with the generated proxy)

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addContosoChatMessageToPage = function (userName, message) {
    console.log(userName + ' ' + message);
};
$.connection.hub.start()
    .done(function(){ console.log('Now connected, connection ID=' + $.connection.hub.id); })
    .fail(function(){ console.log('Could not Connect!'); });
});
```

Alternate way to define method on client (with the generated proxy)

```
$.extend(contosoChatHubProxy.client, {
    addContosoChatMessageToPage: function(userName, message) {
    console.log(userName + ' ' + message);
    };
});
```

Define method on client (without the generated proxy, or when adding after calling the start method)

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
contosoChatHubProxy.on('addContosoChatMessageToPage', function(userName, message) {
    console.log(userName + ' ' + message);
});
connection.start()
    .done(function(){ console.log('Now connected, connection ID=' + connection.id); })
    .fail(function(){ console.log('Could not connect'); });
```

Server code that calls the client method

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addContosoChatMessageToPage(name, message);
    }
}
```

The following examples include a complex object as a method parameter.

Define method on client that takes a complex object (with the generated proxy)

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addMessageToPage = function (message) {
    console.log(message.UserName + ' ' + message.Message);
});
```

Define method on client that takes a complex object (without the generated proxy)

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
chatHubProxy.on('addMessageToPage', function (message) {
    console.log(message.UserName + ' ' + message.Message);
});
```

Server code that defines the complex object

```
public class ContosoChatMessage
{
    public string UserName { get; set; }
    public string Message { get; set; }
}
```

Server code that calls the client method using a complex object

```
public void SendMessage(string name, string message)
{
    Clients.All.addContosoChatMessageToPage(new ContosoChatMessage() { UserName = name, Message = message });
}
```

How to call server methods from the client

To call a server method from the client, use the `server` property of the generated proxy or the `invoke` method on the Hub proxy if you aren't using the generated proxy. The return value or parameters can be complex objects.

Pass in a camel-case version of the method name on the Hub. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions.

The following examples show how to call a server method that doesn't have a return value and how to call a server method that does have a return value.

Server method with no HubMethodName attribute

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(ChatMessage message)
    {
        Clients.All.addContosoChatMessageToPage(message);
    }
}
```

Server code that defines the complex object passed in a parameter

```
public class ChatMessage
{
    public string UserName { get; set; }
    public string Message { get; set; }
}
```

Client code that invokes the server method (with the generated proxy)

```
contosoChatHubProxy.server.newContosoChatMessage({ UserName: userName, Message: message}).done(function () {
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

Client code that invokes the server method (without the generated proxy)

```
contosoChatHubProxy.invoke('newContosoChatMessage', { UserName: userName, Message: message}).done(function ()
{
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

If you decorated the Hub method with a `HubMethodName` attribute, use that name without changing case.

Server method with a HubMethodName attribute

```
public class ContosoChatHub : Hub
{
    [HubMethodName("NewContosoChatMessage")]
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addContosoChatMessageToPage(name, message);
    }
}
```

Client code that invokes the server method (with the generated proxy)

```
contosoChatHubProxy.server.NewContosoChatMessage(userName, message).done(function () {
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

Client code that invokes the server method (without the generated proxy)

```
contosoChatHubProxy.invoke('NewContosoChatMessage', userName, message).done(function () {
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

The preceding examples show how to call a server method that has no return value. The following examples show how to call a server method that has a return value.

Server code for a method that has a return value

```
public class StockTickerHub : Hub
{
    public IEnumerable<Stock> GetAllStocks()
    {
        return _stockTicker.GetAllStocks();
    }
}
```

The Stock class used for the return value

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

Client code that invokes the server method (with the generated proxy)

```
function init() {
    return stockTickerProxy.server.getAllStocks().done(function (stocks) {
        $.each(stocks, function () {
            var stock = this;
            console.log("Symbol=" + stock.Symbol + " Price=" + stock.Price);
        });
    }).fail(function (error) {
        console.log('Error: ' + error);
    });
}
```

Client code that invokes the server method (without the generated proxy)

```
function init() {
    return stockTickerProxy.invoke('getAllStocks').done(function (stocks) {
        $.each(stocks, function () {
            var stock = this;
            console.log("Symbol=" + stock.Symbol + " Price=" + stock.Price);
        });
    }).fail(function (error) {
        console.log('Error: ' + error);
    });
}
```

How to handle connection lifetime events

SignalR provides the following connection lifetime events that you can handle:

- `starting`: Raised before any data is sent over the connection.
- `received`: Raised when any data is received on the connection. Provides the received data.
- `connectionSlow`: Raised when the client detects a slow or frequently dropping connection.
- `reconnecting`: Raised when the underlying transport begins reconnecting.
- `reconnected`: Raised when the underlying transport has reconnected.
- `stateChanged`: Raised when the connection state changes. Provides the old state and the new state (Connecting, Connected, Reconnecting, or Disconnected).
- `disconnected`: Raised when the connection has disconnected.

For example, if you want to display warning messages when there are connection problems that might cause noticeable delays, handle the `connectionSlow` event.

Handle the connectionSlow event (with the generated proxy)

```
$.connection.hub.connectionSlow(function () {
    console.log('We are currently experiencing difficulties with the connection.')
});
```

Handle the connectionSlow event (without the generated proxy)

```
var connection = $.hubConnection();
connection.connectionSlow(function () {
    console.log('We are currently experiencing difficulties with the connection.')
});
```

For more information, see Understanding and Handling Connection Lifetime Events in SignalR.

How to handle errors

The SignalR JavaScript client provides an `error` event that you can add a handler for. You can also use the fail method to add a handler for errors that result from a server method invocation.

If you don't explicitly enable detailed error messages on the server, the exception object that SignalR returns after an error contains minimal information about the error. For example, if a call to `newContosoChatMessage` fails, the error message in the error object contains "`There was an error invoking Hub method 'contosoChatHub.newContosoChatMessage'.`" Sending detailed error messages to clients in production is not recommended for security reasons, but if you want to enable detailed error messages for troubleshooting purposes, use the following code on the server.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableDetailedErrors = true;
RouteTable.Routes.MapHubs(hubConfiguration);
```

The following example shows how to add a handler for the error event.

Add an error handler (with the generated proxy)

```
$.connection.hub.error(function (error) {
    console.log('SignalR error: ' + error)
});
```

Add an error handler (without the generated proxy)

```
var connection = $.hubConnection();
connection.error(function (error) {
    console.log('SignalR error: ' + error)
});
```

The following example shows how to handle an error from a method invocation.

Handle an error from a method invocation (with the generated proxy)

```
contosoChatHubProxy.newContosoChatMessage(userName, message)
    .fail(function(error) {
        console.log( 'newContosoChatMessage error: ' + error)
    });
```

Handle an error from a method invocation (without the generated proxy)

```
contosoChatHubProxy.invoke('newContosoChatMessage', userName, message)
    .fail(function(error) {
        console.log( 'newContosoChatMessage error: ' + error)
    });
```

If a method invocation fails, the `error` event is also raised, so your code in the `error` method handler and in the `.fail` method callback would execute.

How to enable client-side logging

To enable client-side logging on a connection, set the `logging` property on the connection object before you call the `start` method to establish the connection.

Enable logging (with the generated proxy)

```
$.connection.hub.logging = true;
$.connection.hub.start();
```

Enable logging (without the generated proxy)

```
var connection = $.hubConnection();
connection.logging = true;
connection.start();
```

To see the logs, open your browser's developer tools and go to the Console tab. For a tutorial that shows step-by-step instructions and screen shots that show how to do this, see Server Broadcast with ASP.NET Signalr - Enable Logging.

ASP.NET SignalR Hubs API Guide - .NET Client (SignalR 1.x)

2/20/2020 • 14 minutes to read • Edit Online

by Patrick Fletcher, Tom Dykstra

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document provides an introduction to using the Hubs API for SignalR version 2 in .NET clients, such as Windows Store (WinRT), WPF, Silverlight, and console applications.

The SignalR Hubs API enables you to make remote procedure calls (RPCs) from a server to connected clients and from clients to the server. In server code, you define methods that can be called by clients, and you call methods that run on the client. In client code, you define methods that can be called from the server, and you call methods that run on the server. SignalR takes care of all of the client-to-server plumbing for you.

SignalR also offers a lower-level API called Persistent Connections. For an introduction to SignalR, Hubs, and Persistent Connections, or for a tutorial that shows how to build a complete SignalR application, see SignalR - Getting Started.

Overview

This document contains the following sections:

- Client Setup
- How to establish a connection
  - Cross-domain connections from Silverlight clients
- How to configure the connection
  - How to set the maximum number of concurrent connections in WPF clients
  - How to specify query string parameters
  - How to specify the transport method
  - How to specify HTTP headers
  - How to specify client certificates
- How to create the Hub proxy
- How to define methods on the client that the server can call
  - Methods without parameters
  - Methods with parameters, specifying parameter types
  - Methods with parameters, specifying dynamic objects for the parameters
  - How to remove a handler
- How to call server methods from the client
- How to handle connection lifetime events

- How to handle errors
- How to enable client-side logging
- WPF, Silverlight, and console application code samples for client methods that the server can call

For a sample .NET client projects, see the following resources:

- gustavo-armenta / SignalR-Samples on GitHub.com (WinRT, Silverlight, console app examples).
- DamianEdwards / SignalR-MoveShapeDemo / MoveShape.Desktop on GitHub.com (WPF example).
- SignalR / Microsoft.AspNet.SignalR.Client.Samples on GitHub.com (Console app example).

For documentation on how to program the server or JavaScript clients, see the following resources:

- SignalR Hubs API Guide - Server
- SignalR Hubs API Guide - JavaScript Client

Links to API Reference topics are to the .NET 4.5 version of the API. If you're using .NET 4, see the .NET 4 version of the API topics.

Client setup

Install the Microsoft.AspNet.SignalR.Client NuGet package (not the Microsoft.AspNet.SignalR package). This package supports WinRT, Silverlight, WPF, console application, and Windows Phone clients, for both .NET 4 and .NET 4.5.

If the version of SignalR that you have on the client is different from the version that you have on the server, SignalR is often able to adapt to the difference. For example, when SignalR version 2.0 is released and you install that on the server, the server will support clients that have 1.1.x installed as well as clients that have 2.0 installed. If the difference between the version on the server and the version on the client is too great, SignalR throws an `InvalidOperationException` exception when the client tries to establish a connection. The error message is "

```
You are using a version of the client that isn't compatible with the server. Client version X.X, server version X.X
```

".

How to establish a connection

Before you can establish a connection, you have to create a `HubConnection` object and create a proxy. To establish the connection, call the `Start` method on the `HubConnection` object.

```
var hubConnection = new HubConnection("http://www.contoso.com/");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price {1}", stock.Symbol, stock.Price));
await hubConnection.Start();
```

NOTE

For JavaScript clients you have to register at least one event handler before calling the `Start` method to establish the connection. This is not necessary for .NET clients. For JavaScript clients, the generated proxy code automatically creates proxies for all Hubs that exist on the server, and registering a handler is how you indicate which Hubs your client intends to use. But for a .NET client you create Hub proxies manually, so SignalR assumes that you will be using any Hub that you create a proxy for.

The sample code uses the default "/signalr" URL to connect to your SignalR service. For information about how to specify a different base URL, see ASP.NET SignalR Hubs API Guide - Server - The /signalr URL.

The `Start` method executes asynchronously. To make sure that subsequent lines of code don't execute until after the connection is established, use `await` in an ASP.NET 4.5 asynchronous method or `.Wait()` in a synchronous method. Don't use `.Wait()` in a WinRT client.

```
await connection.Start();
```

```
connection.Start().Wait();
```

The `HubConnection` class is thread-safe.

Cross-domain connections from Silverlight clients

For information about how to enable cross-domain connections from Silverlight clients, see Making a Service Available Across Domain Boundaries.

How to configure the connection

Before you establish a connection, you can specify any of the following options:

- Concurrent connections limit.
- Query string parameters.
- The transport method.
- HTTP headers.
- Client certificates.

How to set the maximum number of concurrent connections in WPF clients

In WPF clients, you might have to increase the maximum number of concurrent connections from its default value of 2. The recommended value is 10.

```
var hubConnection = new HubConnection("http://www.contoso.com/");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
ServicePointManager.DefaultConnectionLimit = 10;
await hubConnection.Start();
```

For more information, see ServicePointManager.DefaultConnectionLimit.

How to specify query string parameters

If you want to send data to the server when the client connects, you can add query string parameters to the connection object. The following example shows how to set a query string parameter in client code.

```
var querystringData = new Dictionary<string, string>();
querystringData.Add("contosochatversion", "1.0");
var connection = new HubConnection("http://contoso.com/", querystringData);
```

The following example shows how to read a query string parameter in server code.

```
public class StockTickerHub : Hub
{
    public override Task OnConnected()
    {
        var version = Context.QueryString["contosochatversion"];
        if (version != "1.0")
        {
            Clients.Caller.notifyWrongVersion();
        }
        return base.OnConnected();
    }
}
```

How to specify the transport method

As part of the process of connecting, a SignalR client normally negotiates with the server to determine the best transport that is supported by both server and client. If you already know which transport you want to use, you can bypass this negotiation process. To specify the transport method, pass in a transport object to the Start method. The following example shows how to specify the transport method in client code.

```
var hubConnection = new HubConnection("http://www.contoso.com/");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await hubConnection.Start(new LongPollingTransport());
```

The Microsoft.AspNet.SignalR.Client.Transports namespace includes the following classes that you can use to specify the transport.

- LongPollingTransport
- ServerSentEventsTransport
- WebSocketTransport (Available only when both server and client use .NET 4.5.)
- AutoTransport (Automatically chooses the best transport that is supported by both the client and the server. This is the default transport. Passing this in to the `Start` method has the same effect as not passing in anything.)

The ForeverFrame transport is not included in this list because it is used only by browsers.

For information about how to check the transport method in server code, see ASP.NET SignalR Hubs API Guide - Server - How to get information about the client from the Context property. For more information about transports and fallbacks, see Introduction to SignalR - Transports and Fallbacks.

How to specify HTTP headers

To set HTTP headers, use the `Headers` property on the connection object. The following example shows how to add an HTTP header.

```
hubConnection = new hubConnection("http://www.contoso.com/");
connection.Headers.Add("headername", "headervalue");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await connection.Start();
```

How to specify client certificates

To add client certificates, use the `AddClientCertificate` method on the connection object.

```
hubConnection = new hubConnection("http://www.contoso.com/");
hubConnection.AddClientCertificate(X509Certificate.CreateFromCertFile("MyCert.cer"));
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await connection.Start();
```

How to create the Hub proxy

In order to define methods on the client that a Hub can call from the server, and to invoke methods on a Hub at the server, create a proxy for the Hub by calling `CreateHubProxy` on the connection object. The string you pass in to `CreateHubProxy` is the name of your Hub class, or the name specified by the `HubName` attribute if one was used on the server. Name matching is case-insensitive.

Hub class on server

```
public class StockTickerHub : Hub
```

Create client proxy for the Hub class

```
var hubConnection = new HubConnection("http://www.contoso.com/");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await hubConnection.Start();
```

If you decorate your Hub class with a `HubName` attribute, use that name.

Hub class on server

```
[HubName("stockTicker")]
public class StockTickerHub : Hub
```

Create client proxy for the Hub class

```
var hubConnection = new HubConnection("http://www.contoso.com/");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("stockTicker");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Console.WriteLine("Stock update for {0} new price {1}", stock.Symbol, stock.Price));
await hubConnection.Start();
```

The proxy object is thread-safe. In fact, if you call `HubConnection.CreateHubProxy` multiple times with the same `hubName`, you get the same cached `IHubProxy` object.

How to define methods on the client that the server can call

To define a method that the server can call, use the proxy's `On` method to register an event handler.

Method name matching is case-insensitive. For example, `Clients.All.UpdateStockPrice` on the server will execute `updateStockPrice`, `updatestockprice`, or `UpdateStockPrice` on the client.

Different client platforms have different requirements for how you write method code to update the UI. The examples shown are for WinRT (Windows Store .NET) clients. WPF, Silverlight, and console application examples are provided in a separate section later in this topic.

Methods without parameters

If the method you're handling does not have parameters, use the non-generic overload of the `On` method:

Server code calling client method without parameters

```
public class StockTickerHub : Hub
{
    public void NotifyAllClients()
    {
         Clients.All.Notify();
    }
}
```

WinRT Client code for method called from server without parameters (see WPF and Silverlight examples later in this topic)

```
var hubConnection = new HubConnection("http://www.contoso.com/");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHub.On("notify", () =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += "Notified!\n";
    }, null)
);
await hubConnection.Start();
```

Methods with parameters, specifying the parameter types

If the method you're handling has parameters, specify the types of the parameters as the generic types of the `On` method. There are generic overloads of the `On` method to enable you to specify up to 8 parameters (4 on Windows Phone 7). In the following example, one parameter is sent to the `UpdateStockPrice` method.

Server code calling client method with a parameter

```
public void BroadcastStockPrice(Stock stock)
{
    context.Clients.Others.UpdateStockPrice(stock);
}
```

The Stock class used for the parameter

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

WinRT Client code for a method called from server with a parameter (see WPF and Silverlight examples later in this topic)

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Methods with parameters, specifying dynamic objects for the parameters

As an alternative to specifying parameters as generic types of the `On` method, you can specify parameters as dynamic objects:

Server code calling client method with a parameter

```
public void BroadcastStockPrice(Stock stock)
{
    context.Clients.Others.UpdateStockPrice(stock);
}
```

The Stock class used for the parameter

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

WinRT Client code for a method called from server with a parameter, using a dynamic object for the parameter (see WPF and Silverlight examples later in this topic)

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

How to remove a handler

To remove a handler, call its `Dispose` method.

Client code for a method called from server

```
var updateStockPriceHandler = stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Client code to remove the handler

```
updateStockPriceHandler.Dispose();
```

How to call server methods from the client

To call a method on the server, use the `Invoke` method on the Hub proxy.

If the server method has no return value, use the non-generic overload of the `Invoke` method.

Server code for a method that has no return value

```
public class StockTickerHub : Hub
{
    public void JoinGroup(string groupName)
    {
        Groups.Add(Context.ConnectionId, groupName);
    }
}
```

Client code calling a method that has no return value

```
stockTickerHubProxy.Invoke("JoinGroup", hubConnection.ConnectionID, "SignalRChatRoom");
```

If the server method has a return value, specify the return type as the generic type of the `Invoke` method.

Server code for a method that has a return value and takes a complex type parameter

```
public IEnumerable<Stock> AddStock(Stock stock)
{
    _stockTicker.AddStock(stock);
    return _stockTicker.GetAllStocks();
}
```

The Stock class used for the parameter and return value

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

Client code calling a method that has a return value and takes a complex type parameter, in an ASP.NET 4.5 async method

```
var stocks = await stockTickerHub.Invoke<IEnumerable<Stock>>("AddStock", new Stock() { Symbol = "MSFT" });
foreach (Stock stock in stocks)
{
    textBox.Text += string.Format("Symbol: {0} price: {1}\n", stock.Symbol, stock.Price);
}
```

Client code calling a method that has a return value and takes a complex type parameter, in a synchronous method

```
var stocks = stockTickerHub.Invoke<IEnumerable<Stock>>("AddStock", new Stock() { Symbol = "MSFT" }).Result;
foreach (Stock stock in stocks)
{
    textBox.Text += string.Format("Symbol: {0} price: {1}\n", stock.Symbol, stock.Price);
}
```

The `Invoke` method executes asynchronously and returns a `Task` object. If you don't specify `await` or `.Wait()`, the next line of code will execute before the method that you invoke has finished executing.

How to handle connection lifetime events

SignalR provides the following connection lifetime events that you can handle:

- `Received`: Raised when any data is received on the connection. Provides the received data.
- `ConnectionSlow`: Raised when the client detects a slow or frequently dropping connection.
- `Reconnecting`: Raised when the underlying transport begins reconnecting.
- `Reconnected`: Raised when the underlying transport has reconnected.
- `StateChanged`: Raised when the connection state changes. Provides the old state and the new state. For information about connection state values see ConnectionState Enumeration.
- `Closed`: Raised when the connection has disconnected.

For example, if you want to display warning messages for errors that are not fatal but cause intermittent connection problems, such as slowness or frequent dropping of the connection, handle the `ConnectionSlow` event.

```
hubConnection.ConnectionSlow += () => Console.WriteLine("Connection problems.");
```

For more information, see Understanding and Handling Connection Lifetime Events in SignalR.

How to handle errors

If you don't explicitly enable detailed error messages on the server, the exception object that SignalR returns after an error contains minimal information about the error. For example, if a call to `newContosoChatMessage` fails, the error message in the error object contains "`There was an error invoking Hub method 'contosoChatHub.newContosoChatMessage'.`" Sending detailed error messages to clients in production is not recommended for security reasons, but if you want to enable detailed error messages for troubleshooting purposes, use the following code on the server.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableDetailedErrors = true;
RouteTable.Routes.MapHubs(hubConfiguration);
```

To handle errors that SignalR raises, you can add a handler for the `Error` event on the connection object.

```
hubConnection.Error += ex => Console.WriteLine("SignalR error: {0}", ex.Message);
```

To handle errors from method invocations, wrap the code in a try-catch block.

```
try
{
    IEnumerable<Stock> stocks = await stockTickerHub.Invoke<IEnumerable<Stock>>("GetAllStocks");
    foreach (Stock stock in stocks)
    {
        Console.WriteLine("Symbol: {0} price: {1}", stock.Symbol, stock.Price);
    }
}
catch (Exception ex)
{
    Console.WriteLine("Error invoking GetAllStocks: {0}", ex.Message);
}
```

How to enable client-side logging

To enable client-side logging, set the `TraceLevel` and `TraceWriter` properties on the connection object.

```
var hubConnection = new HubConnection("http://www.contoso.com/");
hubConnection.TraceLevel = TraceLevels.All;
hubConnection.TraceWriter = Console.Out;
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await hubConnection.Start();
```

WPF, Silverlight, and console application code samples for client methods that the server can call

The code samples shown earlier for defining client methods that the server can call apply to WinRT clients. The following samples show the equivalent code for WPF, Silverlight, and console application clients.

Methods without parameters

WPF client code for method called from server without parameters

```
stockTickerHub.On<Stock>("notify", () =>
    Dispatcher.InvokeAsync(() =>
        {
            SignalRTextBlock.Text += string.Format("Notified!");
        })
);
```

Silverlight client code for method called from server without parameters

```
stockTickerHub.On<Stock>("notify", () =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += "Notified!";
    }, null)
);
```

Console application client code for method called from server without parameters

```
stockTickerHubProxyProxy.On("Notify", () => Console.WriteLine("Notified!"));
```

Methods with parameters, specifying the parameter types

WPF client code for a method called from server with a parameter

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Dispatcher.InvokeAsync(() =>
        {
            textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
        })
);
```

Silverlight client code for a method called from server with a parameter

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Console application client code for a method called from server with a parameter

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Console.WriteLine("Symbol {0} Price {1}", stock.Symbol, stock.Price));
```

Methods with parameters, specifying dynamic objects for the parameters

WPF client code for a method called from server with a parameter, using a dynamic object for the parameter

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    Dispatcher.InvokeAsync(() =>
        {
            textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
        })
);
```

Silverlight client code for a method called from server with a parameter, using a dynamic object for the parameter

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Console application client code for a method called from server with a parameter, using a dynamic object for the parameter

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    Console.WriteLine("Symbol {0} Price {1}", stock.Symbol, stock.Price));
```

Understanding and Handling Connection Lifetime Events in SignalR 1.x

2/20/2020 • 16 minutes to read • Edit Online

by Patrick Fletcher, Tom Dykstra

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This article provides an overview of the SignalR connection, reconnection, and disconnection events that you can handle, and timeout and keepalive settings that you can configure.

The article assumes you already have some knowledge of SignalR and connection lifetime events. For an introduction to SignalR, see SignalR - Overview - Getting Started. For lists of connection lifetime events, see the following resources:

- How to handle connection lifetime events in the Hub class
- How to handle connection lifetime events in JavaScript clients
- How to handle connection lifetime events in .NET clients

Overview

This article contains the following sections:

- Connection lifetime terminology and scenarios
  - SignalR connections, transport connections, and physical connections
  - Transport disconnection scenarios
  - Client disconnection scenarios
  - Server disconnection scenarios
- Timeout and keepalive settings
  - ConnectionTimeout
  - DisconnectTimeout
  - KeepAlive
  - How to change timeout and keepalive settings
- How to notify the user about disconnections
- How to continuously reconnect
- How to disconnect a client in server code

Links to API Reference topics are to the .NET 4.5 version of the API. If you're using .NET 4, see the .NET 4 version of the API topics.

Connection lifetime terminology and scenarios

The `OnReconnected` event handler in a SignalR Hub can execute directly after `OnConnected` but not after

`OnDisconnected` for a given client. The reason you can have a reconnection without a disconnection is that there are several ways in which the word "connection" is used in SignalR.

SignalR connections, transport connections, and physical connections

This article will differentiate between *SignalR connections*, *transport connections*, and *physical connections*:

- **SignalR connection** refers to a logical relationship between a client and a server URL, maintained by the SignalR API and uniquely identified by a connection ID. The data about this relationship is maintained by SignalR and is used to establish a transport connection. The relationship ends and SignalR disposes of the data when the client calls the `Stop` method or a timeout limit is reached while SignalR is attempting to re-establish a lost transport connection.
- **Transport connection** refers to a logical relationship between a client and a server, maintained by one of the four transport APIs: WebSockets, server-sent events, forever frame, or long polling. SignalR uses the transport API to create a transport connection, and the transport API depends on the existence of a physical network connection to create the transport connection. The transport connection ends when SignalR terminates it or when the transport API detects that the physical connection is broken.
- **Physical connection** refers to the physical network links -- wires, wireless signals, routers, etc. -- that facilitate communication between a client computer and a server computer. The physical connection must be present in order to establish a transport connection, and a transport connection must be established in order to establish a SignalR connection. However, breaking the physical connection doesn't always immediately end the transport connection or the SignalR connection, as will be explained later in this topic.

In the following diagram, the SignalR connection is represented by the Hubs API and PersistentConnection API SignalR layer, the transport connection is represented by the Transports layer, and the physical connection is represented by the lines between the server and the clients.

When you call the `Start` method in a SignalR client, you are providing SignalR client code with all the information it needs in order to establish a physical connection to a server. SignalR client code uses this information to make an HTTP request and establish a physical connection that uses one of the four transport methods. If the transport connection fails or the server fails, the SignalR connection doesn't go away immediately because the client still has the information it needs to automatically re-establish a new transport connection to the same SignalR URL. In this scenario, no intervention from the user application is involved, and when the SignalR client code establishes a new transport connection, it does not start a new SignalR connection. The continuity of the SignalR connection is reflected in the fact that the connection ID, which is created when you call the `Start` method, does not change.

The `OnReconnected` event handler on the Hub executes when a transport connection is automatically re-established after having been lost. The `OnDisconnected` event handler executes at the end of a SignalR connection. A SignalR connection can end in any of the following ways:

- If the client calls the `Stop` method, a stop message is sent to the server, and both client and server end the

SignalR connection immediately.

- After connectivity between client and server is lost, the client tries to reconnect and the server waits for the client to reconnect. If the attempts to reconnect are unsuccessful and the disconnect timeout period ends, both client and server end the SignalR connection. The client stops trying to reconnect, and the server disposes of its representation of the SignalR connection.
- If the client stops running without having a chance to call the `Stop` method, the server waits for the client to reconnect, and then ends the SignalR connection after the disconnect timeout period.
- If the server stops running, the client tries to reconnect (re-create the transport connection), and then ends the SignalR connection after the disconnect timeout period.

When there are no connection problems, and the user application ends the SignalR connection by calling the `Stop` method, the SignalR connection and the transport connection begin and end at about the same time. The following sections describe in more detail the other scenarios.

Transport disconnection scenarios

Physical connections might be slow or there might be interruptions in connectivity. Depending on factors such as the length of the interruption, the transport connection might be dropped. SignalR then tries to re-establish the transport connection. Sometimes the transport connection API detects the interruption and drops the transport connection, and SignalR finds out immediately that the connection is lost. In other scenarios, neither the transport connection API nor SignalR becomes aware immediately that connectivity has been lost. For all transports except long polling, the SignalR client uses a function called *keepalive* to check for loss of connectivity that the transport API is unable to detect. For information about long polling connections, see Timeout and keepalive settings later in this topic.

When a connection is inactive, periodically the server sends a keepalive packet to the client. As of the date this article is being written, the default frequency is every 10 seconds. By listening for these packets, clients can tell if there is a connection problem. If a keepalive packet is not received when expected, after a short time the client assumes that there are connection problems such as slowness or interruptions. If the keepalive is still not received after a longer time, the client assumes that the connection has been dropped, and it begins trying to reconnect.

The following diagram illustrates the client and server events that are raised in a typical scenario when there are problems with the physical connection that aren't immediately recognized by the transport API. The diagram applies to the following circumstances:

- The transport is WebSockets, forever frame, or server-sent events.
- There are varying periods of interruption in the physical network connection.
- The transport API does not become aware of the interruptions, so SignalR relies on the keepalive functionality to detect them.

If the client goes into reconnecting mode but can't establish a transport connection within the disconnect timeout limit, the server terminates the SignalR connection. When that happens, the server executes the Hub's

`OnDisconnected` method and queues up a disconnect message to send to the client in case the client manages to connect later. If the client then does reconnect, it receives the disconnect command and calls the `Stop` method. In this scenario, `OnReconnected` is not executed when the client reconnects, and `OnDisconnected` is not executed when the client calls `Stop`. The following diagram illustrates this scenario.

The SignalR connection lifetime events that may be raised on the client are the following:

- `ConnectionSlow` client event.

  Raised when a preset proportion of the keepalive timeout period has passed since the last message or keepalive ping was received. The default keepalive timeout warning period is 2/3 of the keepalive timeout. The keepalive timeout is 20 seconds, so the warning occurs at about 13 seconds.

  By default, the server sends keepalive pings every 10 seconds, and the client checks for keepalive pings about every 2 seconds (one third of the difference between the keepalive timeout value and the keepalive timeout warning value).

  If the transport API becomes aware of a disconnection, SignalR might be informed of the disconnection before the keepalive timeout warning period passes. In that case, the `ConnectionSlow` event would not be raised, and SignalR would go directly to the `Reconnecting` event.

- `Reconnecting` client event.

  Raised when (a) the transport API detects that the connection is lost, or (b) the keepalive timeout period has passed since the last message or keepalive ping was received. The SignalR client code begins trying to reconnect. You can handle this event if you want your application to take some action when a transport connection is lost. The default keepalive timeout period is currently 20 seconds.

  If your client code tries to call a Hub method while SignalR is in reconnecting mode, SignalR will try to send the command. Most of the time, such attempts will fail, but in some circumstances they might succeed. For the server-sent events, forever frame, and long polling transports, SignalR uses two communication channels, one that the client uses to send messages and one that it uses to receive messages. The channel used for receiving is the permanently open one, and that's the one that is closed when the physical connection is interrupted. The channel used for sending remains available, so if physical connectivity is restored, a method call from client to server might be successful before the receive channel is re-established. The return value would not be received until SignalR re-opens the channel used for receiving.

- `Reconnected` client event.

  Raised when the transport connection is reestablished. The `OnReconnected` event handler in the Hub executes.

- `Closed` client event (`disconnected` event in JavaScript).

  Raised when the disconnect timeout period expires while the SignalR client code is trying to reconnect after

losing the transport connection. The default disconnect timeout is 30 seconds. (This event is also raised when the connection ends because the `Stop` method is called.)

Transport connection interruptions that are not detected by the transport API and don't delay the reception of keepalive pings from the server for longer than the keepalive timeout warning period might not cause any connection lifetime events to be raised.

Some network environments deliberately close idle connections, and another function of the keepalive packets is to help prevent this by letting these networks know that a SignalR connection is in use. In extreme cases the default frequency of keepalive pings might not be enough to prevent closed connections. In that case you can configure keepalive pings to be sent more often. For more information, see Timeout and keepalive settings later in this topic.

NOTE

IMPORTANT

The sequence of events described here is not guaranteed. SignalR makes every attempt to raise connection lifetime events in a predictable manner according to this scheme, but there are many variations of network events and many ways in which underlying communications frameworks such as transport APIs handle them. For example, the `Reconnected` event might not be raised when the client reconnects, or the `OnConnected` handler on the server might run when the attempt to establish a connection is unsuccessful. This topic describes only the effects that would normally be produced by certain typical circumstances.

Client disconnection scenarios

In a browser client, the SignalR client code that maintains a SignalR connection runs in the JavaScript context of a web page. That's why the SignalR connection has to end when you navigate from one page to another, and that's why you have multiple connections with multiple connection IDs if you connect from multiple browser windows or tabs. When the user closes a browser window or tab, or navigates to a new page or refreshes the page, the SignalR connection immediately ends because SignalR client code handles that browser event for you and calls the `Stop` method. In these scenarios, or in any client platform when your application calls the `Stop` method, the `OnDisconnected` event handler executes immediately on the server and the client raises the `Closed` event (the event is named `disconnected` in JavaScript).

If a client application or the computer that it's running on crashes or goes to sleep (for example, when the user closes the laptop), the server is not informed about what happened. As far as the server knows, the loss of the client might be due to connectivity interruption and the client might be trying to reconnect. Therefore, in these scenarios the server waits to give the client a chance to reconnect, and `OnDisconnected` does not execute until the disconnect timeout period expires (about 30 seconds by default). The following diagram illustrates this scenario.

Server disconnection scenarios

When a server goes offline -- it reboots, fails, the app domain recycles, etc. -- the result might be similar to a lost

connection, or the transport API and SignalR might know immediately that the server is gone, and SignalR might begin trying to reconnect without raising the `ConnectionSlow` event. If the client goes into reconnecting mode, and if the server recovers or restarts or a new server is brought online before the disconnect timeout period expires, the client will reconnect to the restored or new server. In that case, the SignalR connection continues on the client and the `Reconnected` event is raised. On the first server, `OnDisconnected` is never executed, and on the new server, `OnReconnected` is executed although `OnConnected` was never executed for that client on that server before. (The effect is the same if the client reconnects to the same server after a reboot or app domain recycle, because when the server restarts it has no memory of prior connection activity.) The following diagram assumes that the transport API becomes aware of the lost connection immediately, so the `ConnectionSlow` event is not raised.

If a server does not become available within the disconnect timeout period, the SignalR connection ends. In this scenario, the `Closed` event (`disconnected` in JavaScript clients) is raised on the client but `OnDisconnected` is never called on the server. The following diagram assumes that the transport API does not become aware of the lost connection, so it is detected by SignalR keepalive functionality and the `ConnectionSlow` event is raised.

Timeout and keepalive settings

The default `ConnectionTimeout`, `DisconnectTimeout`, and `KeepAlive` values are appropriate for most scenarios but can be changed if your environment has special needs. For example, if your network environment closes connections that are idle for 5 seconds, you might have to decrease the keepalive value.

ConnectionTimeout

This setting represents the amount of time to leave a transport connection open and waiting for a response before closing it and opening a new connection. The default value is 110 seconds.

This setting applies only when keepalive functionality is disabled, which normally applies only to the long polling transport. The following diagram illustrates the effect of this setting on a long polling transport connection.

DisconnectTimeout

This setting represents the amount of time to wait after a transport connection is lost before raising the `Disconnected` event. The default value is 30 seconds. When you set `DisconnectTimeout`, `KeepAlive` is automatically set to 1/3 of the `DisconnectTimeout` value.

KeepAlive

This setting represents the amount of time to wait before sending a keepalive packet over an idle connection. The default value is 10 seconds. This value must not be more than 1/3 of the `DisconnectTimeout` value.

If you want to set both `DisconnectTimeout` and `KeepAlive`, set `KeepAlive` after `DisconnectTimeout`. Otherwise your `KeepAlive` setting will be overwritten when `DisconnectTimeout` automatically sets `KeepAlive` to 1/3 of the timeout value.

If you want to disable keepalive functionality, set `KeepAlive` to null. Keepalive functionality is automatically disabled for the long polling transport.

How to change timeout and keepalive settings

To change the default values for these settings, set them in `Application_Start` in your *Global.asax* file, as shown in the following example. The values shown in the sample code are the same as the default values.

```
protected void Application_Start(object sender, EventArgs e)
{
    // Make long polling connections wait a maximum of 110 seconds for a
    // response. When that time expires, trigger a timeout command and
    // make the client reconnect.
    GlobalHost.Configuration.ConnectionTimeout = TimeSpan.FromSeconds(110);

    // Wait a maximum of 30 seconds after a transport connection is lost
    // before raising the Disconnected event to terminate the SignalR connection.
    GlobalHost.Configuration.DisconnectTimeout = TimeSpan.FromSeconds(30);

    // For transports other than long polling, send a keepalive packet every
    // 10 seconds.
    // This value must be no more than 1/3 of the DisconnectTimeout value.
    GlobalHost.Configuration.KeepAlive = TimeSpan.FromSeconds(10);
}
```

How to notify the user about disconnections

In some applications you might want to display a message to the user when there are connectivity problems. You have several options for how and when to do this. The following code samples are for a JavaScript client using the generated proxy.

- Handle the `connectionSlow` event to display a message as soon as SignalR is aware of connection problems,

before it goes into reconnecting mode.

```
$.connection.hub.connectionSlow(function() {
    notifyUserOfConnectionProblem(); // Your function to notify user.
});
```

- Handle the `reconnecting` event to display a message when SignalR is aware of a disconnection and is going into reconnecting mode.

```
$.connection.hub.reconnecting(function() {
    notifyUserOfTryingToReconnect(); // Your function to notify user.
});
```

- Handle the `disconnected` event to display a message when an attempt to reconnect has timed out. In this scenario, the only way to re-establish a connection with the server again is to restart the SignalR connection by calling the `Start` method, which will create a new connection ID. The following code sample uses a flag to make sure that you issue the notification only after a reconnecting timeout, not after a normal end to the SignalR connection caused by calling the `Stop` method.

```
var tryingToReconnect = false;

$.connection.hub.reconnecting(function() {
    tryingToReconnect = true;
});

$.connection.hub.reconnected(function() {
    tryingToReconnect = false;
});

$.connection.hub.disconnected(function() {
    if(tryingToReconnect) {
        notifyUserOfDisconnect(); // Your function to notify user.
    }
});
```

How to continuously reconnect

In some applications you might want to automatically re-establish a connection after it has been lost and the attempt to reconnect has timed out. To do that, you can call the `Start` method from your `Closed` event handler (`disconnected` event handler on JavaScript clients). You might want to wait a period of time before calling `Start` in order to avoid doing this too frequently when the server or the physical connection are unavailable. The following code sample is for a JavaScript client using the generated proxy.

```
$.connection.hub.disconnected(function() {
   setTimeout(function() {
       $.connection.hub.start();
   }, 5000); // Restart connection after 5 seconds.
});
```

A potential problem to be aware of in mobile clients is that continuous reconnection attempts when the server or physical connection isn't available could cause unnecessary battery drain.

How to disconnect a client in server code

SignalR version 1.1.1 does not have a built-in server API for disconnecting clients. There are plans for adding this

functionality in the future. In the current SignalR release, the simplest way to disconnect a client from the server is to implement a disconnect method on the client and call that method from the server. The following code sample shows a disconnect method for a JavaScript client using the generated proxy.

```
var myHubProxy = $.connection.myHub
myHubProxy.client.stopClient = function() {
    $.connection.hub.stop();
};
```

WARNING

Security - Neither this method for disconnecting clients nor the proposed built-in API will address the scenario of hacked clients that are running malicious code, since the clients could reconnect or the hacked code might remove the `stopClient` method or change what it does. The appropriate place to implement stateful denial-of-service (DOS) protection is not in the framework or the server layer, but rather in front-end infrastructure.

Working with Groups in SignalR 1.x

2/20/2020 • 8 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to add users to groups and persist group membership information.

Overview

Groups in SignalR provide a method for broadcasting messages to specified subsets of connected clients. A group can have any number of clients, and a client can be a member of any number of groups. You don't have to explicitly create groups. In effect, a group is automatically created the first time you specify its name in a call to Groups.Add, and it is deleted when you remove the last connection from membership in it. For an introduction to using groups, see How to manage group membership from the Hub class in the Hubs API - Server Guide.

There is no API for getting a group membership list or a list of groups. SignalR sends messages to clients and groups based on a pub/sub model, and the server does not maintain lists of groups or group memberships. This helps maximize scalability, because whenever you add a node to a web farm, any state that SignalR maintains has to be propagated to the new node.

When you add a user to a group using the `Groups.Add` method, the user receives messages directed to that group for the duration of the current connection, but the user's membership in that group is not persisted beyond the current connection. If you want to permanently retain information about groups and group membership, you must store that data in a repository such as a database or Azure table storage. Then, each time a user connects to your application, you retrieve from the repository which groups the user belongs to, and manually add that user to those groups.

When reconnecting after a temporary disruption, the user automatically re-joins the previously-assigned groups. Automatically rejoining a group only applies when reconnecting, not when establishing a new connection. A digitally-signed token is passed from the client that contains the list of previously-assigned groups. If you want to verify whether the user belongs to the requested groups, you can override the default behavior.

This topic includes the following sections:

- Adding and removing users
- Calling members of a group
- Storing group membership in a database
- Storing group membership in Azure table storage
- Verifying group membership when reconnecting

Adding and removing users

To add or remove users from a group, you call the Add or Remove methods, and pass in the user's connection id and group's name as parameters. You do not need to manually remove a user from a group when the connection ends.

The following example shows the `Groups.Add` and `Groups.Remove` methods used in Hub methods.

```
public class ContosoChatHub : Hub
{
    public Task JoinRoom(string roomName)
    {
        return Groups.Add(Context.ConnectionId, roomName);
    }

    public Task LeaveRoom(string roomName)
    {
        return Groups.Remove(Context.ConnectionId, roomName);
    }
}
```

The `Groups.Add` and `Groups.Remove` methods execute asynchronously.

If you want to add a client to a group and immediately send a message to the client by using the group, you have to make sure that the Groups.Add method finishes first. The following code examples show how to do that, one by using code that works in .NET 4.5, and one by using code that works in .NET 4.

Asynchronous .NET 4.5 Example

```
public async Task JoinRoom(string roomName)
{
    await Groups.Add(Context.ConnectionId, roomName);
    Clients.Group(roomName).addChatMessage(Context.User.Identity.Name + " joined.");
}
```

Asynchronous .NET 4 Example

```
public void JoinRoom(string roomName)
{
    (Groups.Add(Context.ConnectionId, roomName) as Task).ContinueWith(antecedent =>
      Clients.Group(roomName).addChatMessage(Context.User.Identity.Name + " joined."));
}
```

In general, you should not include `await` when calling the `Groups.Remove` method because the connection id that you are trying to remove might no longer be available. In that case, `TaskCanceledException` is thrown after the request times out. If your application must ensure that the user has been removed from the group before sending a message to the group, you can add `await` before Groups.Remove, and then catch the `TaskCanceledException` exception that might be thrown.

Calling members of a group

You can send messages to all of the members of a group or only specified members of the group, as shown in the following examples.

- **All** connected clients in a specified group.

  ```
  Clients.Group(groupName).addChatMessage(name, message);
  ```

- All connected clients in a specified group **except the specified clients**, identified by connection ID.

  ```
  Clients.Group(groupName, connectionId1, connectionId2).addChatMessage(name, message);
  ```

- All connected clients in a specified group **except the calling client**.

```
Clients.OthersInGroup(groupName).addChatMessage(name, message);
```

Storing group membership in a database

The following examples show how to retain group and user information in a database. You can use any data access technology; however, the example below shows how to define models using Entity Framework. These entity models correspond to database tables and fields. Your data structure could vary considerably depending on the requirements of your application. This example includes a class named `ConversationRoom` which would be unique to an application that enables users to join conversations about different subjects, such as sports or gardening. This example also includes a class for the connections. The connection class is not absolutely required for tracking group membership but is frequently part of robust solution to tracking users.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.Data.Entity;

namespace GroupsExample
{
    public class UserContext : DbContext
    {
        public DbSet<User> Users { get; set; }
        public DbSet<Connection> Connections { get; set; }
        public DbSet<ConversationRoom> Rooms { get; set; }
    }

    public class User
    {
        [Key]
        public string UserName { get; set; }
        public ICollection<Connection> Connections { get; set; }
        public virtual ICollection<ConversationRoom> Rooms { get; set; }
    }

    public class Connection
    {
        public string ConnectionID { get; set; }
        public string UserAgent { get; set; }
        public bool Connected { get; set; }
    }

    public class ConversationRoom
    {
        [Key]
        public string RoomName { get; set; }
        public virtual ICollection<User> Users { get; set; }
    }
}
```

Then, in the hub, you can retrieve the group and user information from the database and manually add the user to the appropriate groups. The example does not include code for tracking the user connections. In this example, the `await` keyword is not applied before `Groups.Add` because a message is not immediately sent to members of the group. If you want to send a message to all members of the group immediately after adding the new member, you would want to apply the `await` keyword to make sure the asynchronous operation has completed.

```
using Microsoft.AspNet.SignalR;
using System;
using System.Collections.Generic;
using System.Data.Entity;
using System.Linq;
```

```
using System.Threading.Tasks;

namespace GroupsExample
{
    [Authorize]
    public class ChatHub : Hub
    {
        public override Task OnConnected()
        {
            using (var db = new UserContext())
            {
                // Retrieve user.
                var user = db.Users
                    .Include(u => u.Rooms)
                    .SingleOrDefault(u => u.UserName == Context.User.Identity.Name);

                // If user does not exist in database, must add.
                if (user == null)
                {
                    user = new User()
                    {
                        UserName = Context.User.Identity.Name
                    };
                    db.Users.Add(user);
                    db.SaveChanges();
                }
                else
                {
                    // Add to each assigned group.
                    foreach (var item in user.Rooms)
                    {
                        Groups.Add(Context.ConnectionId, item.RoomName);
                    }
                }
            }
            return base.OnConnected();
        }

        public void AddToRoom(string roomName)
        {
            using (var db = new UserContext())
            {
                // Retrieve room.
                var room = db.Rooms.Find(roomName);

                if (room != null)
                {
                    var user = new User() { UserName = Context.User.Identity.Name};
                    db.Users.Attach(user);

                    room.Users.Add(user);
                    db.SaveChanges();
                    Groups.Add(Context.ConnectionId, roomName);
                }
            }
        }

        public void RemoveFromRoom(string roomName)
        {
            using (var db = new UserContext())
            {
                // Retrieve room.
                var room = db.Rooms.Find(roomName);
                if (room != null)
                {
                    var user = new User() { UserName = Context.User.Identity.Name };
                    db.Users.Attach(user);

                    room.Users.Remove(user);
```

```
                    db.SaveChanges();

                    Groups.Remove(Context.ConnectionId, roomName);
                }
            }
        }
    }
}
```

Storing group membership in Azure table storage

Using Azure table storage to store group and user information is similar to using a database. The following example shows a table entity that stores the user name and group name.

```
using Microsoft.WindowsAzure.Storage.Table;
using System;

namespace GroupsExample
{
    public class UserGroupEntity : TableEntity
    {
        public UserGroupEntity() { }

        public UserGroupEntity(string userName, string groupName)
        {
            this.PartitionKey = userName;
            this.RowKey = groupName;
        }
    }
}
```

In the hub, you retrieve the assigned groups when the user connects.

```
using Microsoft.AspNet.SignalR;
using System;
using System.Collections.Generic;
using System.Threading.Tasks;
using Microsoft.WindowsAzure.Storage.Table;
using Microsoft.WindowsAzure.Storage;
using Microsoft.WindowsAzure;

namespace GroupsExample
{
    [Authorize]
    public class ChatHub : Hub
    {
        public override Task OnConnected()
        {
            string userName = Context.User.Identity.Name;

            var table = GetRoomTable();
            table.CreateIfNotExists();
            var query = new TableQuery<UserGroupEntity>()
                .Where(TableQuery.GenerateFilterCondition(
                "PartitionKey", QueryComparisons.Equal, userName));

            foreach (var entity in table.ExecuteQuery(query))
            {
                Groups.Add(Context.ConnectionId, entity.RowKey);
            }

            return base.OnConnected();
        }
```

```
        public Task AddToRoom(string roomName)
        {
            string userName = Context.User.Identity.Name;

            var table = GetRoomTable();

            var insertOperation = TableOperation.InsertOrReplace(
                new UserGroupEntity(userName, roomName));
            table.Execute(insertOperation);

            return Groups.Add(Context.ConnectionId, roomName);
        }

        public Task RemoveFromRoom(string roomName)
        {
            string userName = Context.User.Identity.Name;

            var table = GetRoomTable();

            var retrieveOperation = TableOperation.Retrieve<UserGroupEntity>(
                userName, roomName);
            var retrievedResult = table.Execute(retrieveOperation);

            var deleteEntity = (UserGroupEntity)retrievedResult.Result;

            if (deleteEntity != null)
            {
                var deleteOperation = TableOperation.Delete(deleteEntity);
                table.Execute(deleteOperation);
            }

            return Groups.Remove(Context.ConnectionId, roomName);
        }

       private CloudTable GetRoomTable()
        {
            var storageAccount =
                CloudStorageAccount.Parse(
                CloudConfigurationManager.GetSetting("StorageConnectionString"));
            var tableClient = storageAccount.CreateCloudTableClient();
            return tableClient.GetTableReference("room");
        }
    }
}
```

Verifying group membership when reconnecting

By default, SignalR automatically re-assigns a user to the appropriate groups when reconnecting from a temporary disruption, such as when a connection is dropped and re-established before the connection times out. The user's group information is passed in a token when reconnecting, and that token is verified on the server. For information about the verification process for rejoining users to groups, see Rejoining groups when reconnecting.

In general, you should use the default behavior of automatically rejoining groups on reconnect. SignalR groups are not intended as a security mechanism for restricting access to sensitive data. However, if your application must double-check a user's group membership when reconnecting, you can override the default behavior. Changing the default behavior can add a burden to your database because a user's group membership must be retrieved for each reconnection rather than just when the user connects.

If you must verify group membership on reconnect, create a new hub pipeline module that returns a list of assigned groups, as shown below.

```
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;
using System;
using System.Collections.Generic;
using System.Data.Entity;
using System.Linq;

namespace GroupsExample
{
    public class RejoingGroupPipelineModule : HubPipelineModule
    {
        public override Func<HubDescriptor, IRequest, IList<string>, IList<string>>
            BuildRejoiningGroups(Func<HubDescriptor, IRequest, IList<string>, IList<string>>
            rejoiningGroups)
        {
            rejoiningGroups = (hb, r, l) =>
            {
                List<string> assignedRooms = new List<string>();
                using (var db = new UserContext())
                {
                    var user = db.Users.Include(u => u.Rooms)
                        .Single(u => u.UserName == r.User.Identity.Name);
                    foreach (var item in user.Rooms)
                    {
                        assignedRooms.Add(item.RoomName);
                    }
                }
                return assignedRooms;
            };

            return rejoiningGroups;
        }
    }
}
```

Then, add that module to the hub pipeline, as highlighted below.

```
public class Global : HttpApplication
{
    void Application_Start(object sender, EventArgs e)
    {
        // Code that runs on application startup
        BundleConfig.RegisterBundles(BundleTable.Bundles);
        AuthConfig.RegisterOpenAuth();
        RouteConfig.RegisterRoutes(RouteTable.Routes);
        RouteTable.Routes.MapHubs();
        GlobalHost.HubPipeline.AddModule(new RejoingGroupPipelineModule());
    }
}
```

Mapping SignalR Users to Connections in SignalR 1.x

2/20/2020 • 7 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

> This topic shows how to retain information about users and their connections.

Introduction

Each client connecting to a hub passes a unique connection id. You can retrieve this value in the `Context.ConnectionId` property of the hub context. If your application needs to map a user to the connection id and persist that mapping, you can use one of the following:

- In-memory storage, such as a dictionary
- SignalR group for each user
- Permanent, external storage, such as a database table or Azure table storage

Each of these implementations is shown in this topic. You use the `OnConnected`, `OnDisconnected`, and `OnReconnected` methods of the `Hub` class to track the user connection status.

The best approach for your application depends on:

- The number of web servers hosting your application.
- Whether you need to get a list of the currently connected users.
- Whether you need to persist group and user information when the application or server restarts.
- Whether the latency of calling an external server is an issue.

The following table shows which approach works for these considerations.

	MORE THAN ONE SERVER	GET LIST OF CURRENTLY CONNECTED USERS	PERSIST INFORMATION AFTER RESTARTS	OPTIMAL PERFORMANCE
In-memory		✓		✓
Single-user groups	✓			✓
Permanent, external	✓	✓	✓	

In-memory storage

The following examples show how to retain connection and user information in a dictionary that is stored in memory. The dictionary uses a `HashSet` to store the connection id. At any time a user could have more than one connection to the SignalR application. For example, a user who is connected through multiple devices or more than one browser tab would have more than one connection id.

If the application shuts down, all of the information is lost, but it will be re-populated as the users re-establish their connections. In-memory storage does not work if your environment includes more than one web server because each server would have a separate collection of connections.

The first example shows a class that manages the mapping of users to connections. The key for the HashSet will be the user's name.

```
using System.Collections.Generic;
using System.Linq;

namespace BasicChat
{
    public class ConnectionMapping<T>
    {
        private readonly Dictionary<T, HashSet<string>> _connections =
            new Dictionary<T, HashSet<string>>();

        public int Count
        {
            get
            {
                return _connections.Count;
            }
        }

        public void Add(T key, string connectionId)
        {
            lock (_connections)
            {
                HashSet<string> connections;
                if (!_connections.TryGetValue(key, out connections))
                {
                    connections = new HashSet<string>();
                    _connections.Add(key, connections);
                }

                lock (connections)
                {
                    connections.Add(connectionId);
                }
            }
        }

        public IEnumerable<string> GetConnections(T key)
        {
            HashSet<string> connections;
            if (_connections.TryGetValue(key, out connections))
            {
                return connections;
            }

            return Enumerable.Empty<string>();
        }

        public void Remove(T key, string connectionId)
        {
            lock (_connections)
            {
                HashSet<string> connections;
                if (!_connections.TryGetValue(key, out connections))
                {
                    return;
                }

                lock (connections)
                {
                    connections.Remove(connectionId);
```

```
                    if (connections.Count == 0)
                    {
                        _connections.Remove(key);
                    }
                }
            }
        }
    }
}
```

The next example shows how to use the connection mapping class from a hub. The instance of the class is stored in a variable name `_connections`.

```
using System.Threading.Tasks;
using Microsoft.AspNet.SignalR;

namespace BasicChat
{
    [Authorize]
    public class ChatHub : Hub
    {
        private readonly static ConnectionMapping<string> _connections =
            new ConnectionMapping<string>();

        public void SendChatMessage(string who, string message)
        {
            string name = Context.User.Identity.Name;

            foreach (var connectionId in _connections.GetConnections(who))
            {
                Clients.Client(connectionId).addChatMessage(name + ": " + message);
            }
        }

        public override Task OnConnected()
        {
            string name = Context.User.Identity.Name;

            _connections.Add(name, Context.ConnectionId);

            return base.OnConnected();
        }

        public override Task OnDisconnected()
        {
            string name = Context.User.Identity.Name;

            _connections.Remove(name, Context.ConnectionId);

            return base.OnDisconnected();
        }

        public override Task OnReconnected()
        {
            string name = Context.User.Identity.Name;

            if (!_connections.GetConnections(name).Contains(Context.ConnectionId))
            {
                _connections.Add(name, Context.ConnectionId);
            }

            return base.OnReconnected();
        }
    }
}
```

Single-user groups

You can create a group for each user, and then send a message to that group when you want to reach only that user. The name of each group is the name of the user. If a user has more than one connection, each connection id is added to the user's group.

You should not manually remove the user from the group when the user disconnects. This action is automatically performed by the SignalR framework.

The following example shows how to implement single-user groups.

```
using Microsoft.AspNet.SignalR;
using System;
using System.Threading.Tasks;

namespace BasicChat
{
    [Authorize]
    public class ChatHub : Hub
    {
        public void SendChatMessage(string who, string message)
        {
            string name = Context.User.Identity.Name;

            Clients.Group(who).addChatMessage(name + ": " + message);
        }

        public override Task OnConnected()
        {
            string name = Context.User.Identity.Name;

            Groups.Add(Context.ConnectionId, name);

            return base.OnConnected();
        }
    }
}
```

Permanent, external storage

This topic shows how to use either a database or Azure table storage for storing connection information. This approach works when you have multiple web servers because each web server can interact with the same data repository. If your web servers stop working or the application restarts, the `OnDisconnected` method is not called. Therefore, it is possible that your data repository will have records for connection ids that are no longer valid. To clean up these orphaned records, you may wish to invalidate any connection that was created outside of a timeframe that is relevant to your application. The examples in this section include a value for tracking when the connection was created, but do not show how to clean up old records because you may want to do that as background process.

Database

The following examples show how to retain connection and user information in a database. You can use any data access technology; however, the example below shows how to define models using Entity Framework. These entity models correspond to database tables and fields. Your data structure could vary considerably depending on the requirements of your application.

The first example shows how to define a user entity that can be associated with many connection entities.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.Data.Entity;

namespace MapUsersSample
{
    public class UserContext : DbContext
    {
        public DbSet<User> Users { get; set; }
        public DbSet<Connection> Connections { get; set; }
    }

    public class User
    {
        [Key]
        public string UserName { get; set; }
        public ICollection<Connection> Connections { get; set; }
    }

    public class Connection
    {
        public string ConnectionID { get; set; }
        public string UserAgent { get; set; }
        public bool Connected { get; set; }
    }
}
```

Then, from the hub, you can track the state of each connection with the code shown below.

```
using System;
using System.Data.Entity;
using System.Linq;
using System.Threading.Tasks;
using System.Collections.Concurrent;
using Microsoft.AspNet.SignalR;

namespace MapUsersSample
{
    [Authorize]
    public class ChatHub : Hub
    {
        public void SendChatMessage(string who, string message)
        {
            var name = Context.User.Identity.Name;
            using (var db = new UserContext())
            {
                var user = db.Users.Find(who);
                if (user == null)
                {
                    Clients.Caller.showErrorMessage("Could not find that user.");
                }
                else
                {
                    db.Entry(user)
                        .Collection(u => u.Connections)
                        .Query()
                        .Where(c => c.Connected == true)
                        .Load();

                    if (user.Connections == null)
                    {
                        Clients.Caller.showErrorMessage("The user is no longer connected.");
                    }
                    else
                    {
```

```
                        foreach (var connection in user.Connections)
                        {
                            Clients.Client(connection.ConnectionID)
                                .addChatMessage(name + ": " + message);
                        }
                    }
                }
            }
        }

        public override Task OnConnected()
        {
            var name = Context.User.Identity.Name;
            using (var db = new UserContext())
            {
                var user = db.Users
                    .Include(u => u.Connections)
                    .SingleOrDefault(u => u.UserName == name);

                if (user == null)
                {
                    user = new User
                    {
                        UserName = name,
                        Connections = new List<Connection>()
                    };
                    db.Users.Add(user);
                }

                user.Connections.Add(new Connection
                {
                    ConnectionID = Context.ConnectionId,
                    UserAgent = Context.Request.Headers["User-Agent"],
                    Connected = true
                });
                db.SaveChanges();
            }
            return base.OnConnected();
        }

        public override Task OnDisconnected()
        {
            using (var db = new UserContext())
            {
                var connection = db.Connections.Find(Context.ConnectionId);
                connection.Connected = false;
                db.SaveChanges();
            }
            return base.OnDisconnected();
        }
    }
}
```

Azure table storage

The following Azure table storage example is similar to the database example. It does not include all of the information that you would need to get started with Azure Table Storage Service. For information, see How to use Table storage from .NET.

The following example shows a table entity for storing connection information. It partitions the data by user name, and identifies each entity by the connection id, so a user can have multiple connections at any time.

```
using Microsoft.WindowsAzure.Storage.Table;
using System;

namespace MapUsersSample
{
    public class ConnectionEntity : TableEntity
    {
        public ConnectionEntity() { }

        public ConnectionEntity(string userName, string connectionID)
        {
            this.PartitionKey = userName;
            this.RowKey = connectionID;
        }
    }
}
```

In the hub, you track the status of each user's connection.

```
using Microsoft.AspNet.SignalR;
using Microsoft.WindowsAzure;
using Microsoft.WindowsAzure.Storage;
using Microsoft.WindowsAzure.Storage.Table;
using System;
using System.Linq;
using System.Threading.Tasks;

namespace MapUsersSample
{
    public class ChatHub : Hub
    {
        public void SendChatMessage(string who, string message)
        {
            var name = Context.User.Identity.Name;

            var table = GetConnectionTable();

            var query = new TableQuery<ConnectionEntity>()
                .Where(TableQuery.GenerateFilterCondition(
                "PartitionKey",
                QueryComparisons.Equal,
                who));

            var queryResult = table.ExecuteQuery(query).ToList();
            if (queryResult.Count == 0)
            {
                Clients.Caller.showErrorMessage("The user is no longer connected.");
            }
            else
            {
                foreach (var entity in queryResult)
                {
                    Clients.Client(entity.RowKey).addChatMessage(name + ": " + message);
                }
            }
        }

        public override Task OnConnected()
        {
            var name = Context.User.Identity.Name;
            var table = GetConnectionTable();
            table.CreateIfNotExists();

            var entity = new ConnectionEntity(
                name.ToLower(),
                Context.ConnectionId);
```

```
            var insertOperation = TableOperation.InsertOrReplace(entity);
            table.Execute(insertOperation);

            return base.OnConnected();
        }

        public override Task OnDisconnected()
        {
            var name = Context.User.Identity.Name;
            var table = GetConnectionTable();

            var deleteOperation = TableOperation.Delete(
                new ConnectionEntity(name, Context.ConnectionId) { ETag = "*" });
            table.Execute(deleteOperation);

            return base.OnDisconnected();
        }

        private CloudTable GetConnectionTable()
        {
            var storageAccount =
                CloudStorageAccount.Parse(
                CloudConfigurationManager.GetSetting("StorageConnectionString"));
            var tableClient = storageAccount.CreateCloudTableClient();
            return tableClient.GetTableReference("connection");
        }
    }
}
```

Introduction to SignalR Security (SignalR 1.x)

2/20/2020 • 10 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

> This article describes the security issues you must consider when developing a SignalR application.

Overview

This document contains the following sections:

- SignalR Security Concepts
  - Authentication and authorization
  - Connection token
  - Rejoining groups when reconnecting
- How SignalR prevents Cross-Site Request Forgery
- SignalR Security Recommendations
  - Secure Socket Layers (SSL) protocol
  - Do not use groups as a security mechanism
  - Safely handling input from clients
  - Reconciling a change in user status with an active connection
  - Automatically generated JavaScript proxy files
  - Exceptions

SignalR Security Concepts

Authentication and authorization

SignalR is designed to be integrated into the existing authentication structure for an application. It does not provide any features for authenticating users. Instead, you authenticate users as you would normally in your application, and then work with the results of the authentication in your SignalR code. For example, you might authenticate your users with ASP.NET forms authentication, and then in your hub, enforce which users or roles are authorized to call a method. In your hub, you can also pass authentication information, such as user name or whether a user belongs to a role, to the client.

SignalR provides the Authorize attribute to specify which users have access to a hub or method. You apply the Authorize attribute to either a hub or particular methods in a hub. Without the Authorize attribute, all public methods on the hub are available to a client that is connected to the hub. For more information about hubs, see Authentication and Authorization for SignalR Hubs.

The `Authorize` attribute is used only with hubs. To enforce authorization rules when using a `PersistentConnection` you must override the `AuthorizeRequest` method. For more information about persistent connections, see Authentication and Authorization for SignalR Persistent Connections.

Connection token

SignalR mitigates the risk of executing malicious commands by validating the identity of the sender. A connection token, containing the connection id and username for authenticated users, is passed between the client and server for each request. The connection id is a unique identifier that is randomly generated by the server when a new connection is created, and is persisted for the duration of the connection. The username is provided by the authentication mechanism for the web application. The connection token is protected with encryption and a digital signature.

For each request, the server validates the contents of the token to ensure that the request is coming from the specified user. The username must correspond to the connection id. By validating both the connection id and the username, SignalR prevents a malicious user from easily impersonating another user. If the server cannot validate the connection token, the request fails.

Because the connection id is part of the verification process, you should not reveal one user's connection id to other users or store the value on the client, such as in a cookie.

Rejoining groups when reconnecting

By default, the SignalR application will automatically re-assign a user to the appropriate groups when reconnecting from a temporary disruption, such as when a connection is dropped and re-established before the connection times out. When reconnecting, the client passes a group token that includes the connection id and the assigned groups. The group token is digitally signed and encrypted. The client retains the same connection id after a reconnection; therefore, the connection id passed from the reconnected client must match the previous connection id used by the client. This verification prevents a malicious user from passing requests to join unauthorized groups when reconnecting.

However, it is important to note, that the group token does not expire. If a user belonged to a group in the past, but was banned from that group, that user may be able to mimic a group token that includes the prohibited group. If

you need to securely manage which users belong to which groups, you need to store that data on the server, such as in a database. Then, add logic to your application that verifies on the server whether a user belongs to a group. For an example of verifying group membership, see Working with groups.

Automatically rejoining groups only applies when a connection is reconnected after a temporary disruption. If a user disconnects by navigating away from the application or the application restarts, your application must handle how to add that user to the correct groups. For more information, see Working with groups.

How SignalR prevents Cross-Site Request Forgery

Cross-Site Request Forgery (CSRF) is an attack where a malicious site sends a request to a vulnerable site where the user is currently logged in. SignalR prevents CSRF by making it extremely unlikely for a malicious site to create a valid request for your SignalR application.

Description of CSRF attack

Here is an example of a CSRF attack:

1. A user logs into `www.example.com`, using forms authentication.
2. The server authenticates the user. The response from the server includes an authentication cookie.
3. Without logging out, the user visits a malicious web site. This malicious site contains the following HTML form:

   ```
   <h1>You Are a Winner!</h1>
   <form action="http://example.com/api/account" method="post">
       <input type="hidden" name="Transaction" value="withdraw" />
       <input type="hidden" name="Amount" value="1000000" />
       <input type="submit" value="Click Me"/>
   </form>
   ```

   Notice that the form action posts to the vulnerable site, not to the malicious site. This is the "cross-site" part of CSRF.
4. The user clicks the submit button. The browser includes the authentication cookie with the request.
5. The request runs on the example.com server with the user's authentication context, and can do anything that an authenticated user is allowed to do.

Although this example requires the user to click the form button, the malicious page could just as easily run a script that sends an AJAX request to your SignalR application. Moreover, using SSL does not prevent a CSRF attack, because the malicious site can send an "https://" request.

Typically, CSRF attacks are possible against web sites that use cookies for authentication, because browsers send all relevant cookies to the destination web site. However, CSRF attacks are not limited to exploiting cookies. For example, Basic and Digest authentication are also vulnerable. After a user logs in with Basic or Digest authentication, the browser automatically sends the credentials until the session ends.

CSRF mitigations taken by SignalR

SignalR takes the following steps to prevent a malicious site from creating valid requests to your SignalR application. These steps are taken by default and do not require any action in your code.

- **Disable cross domain requests**
  By default, cross domain requests are disabled in a SignalR application to prevent users from calling a SignalR endpoint from an external domain. Any request that comes from an external domain is automatically considered invalid and is blocked. It is recommended that you keep this default behavior; otherwise, a malicious site could trick users into sending commands to your site. If you need to use cross domain requests,

see How to establish a cross-domain connection .

- **Pass connection token in query string, not cookie**
  SignalR passes the connection token as a query string value, instead of as a cookie. By not storing the connection token as a cookie, the connection token is not inadvertently forwarded by the browser when malicious code is encountered. Also, the connection token is not persisted beyond the current connection. Therefore, a malicious user cannot make a request under another user's authentication credentials.
- **Verify connection token**
  As described in the Connection token section, the server knows which connection id is associated with each authenticated user. The server does not process any request from a connection id that does not match the user name. It is unlikely a malicious user could guess a valid request because the malicious user would have to know the user name and the current randomly-generated connection id. That connection id becomes invalid as soon as the connection is ended. Anonymous users should not have access to any sensitive information.

SignalR Security Recommendations

Secure Socket Layers (SSL) protocol

The SSL protocol uses encryption to secure the transport of data between a client and server. If your SignalR application transmits sensitive information between the client and server, use SSL for the transport. For more information about setting up SSL, see How to set up SSL on IIS 7.

Do not use groups as a security mechanism

Groups are a convenient way of collecting related users, but they are not a secure mechanism for limiting access to sensitive information. This is especially true when users can automatically rejoin groups during a reconnect. Instead, consider adding privileged users to a role and limiting access to a hub method to only members of that role. For an example of restricting access based on a role, see Authentication and Authorization for SignalR Hubs. For an example of checking user access to groups when reconnecting, see Working with groups.

Safely handling input from clients

All input from clients that is intended for broadcast to other clients must be encoded to ensure that a malicious user does not send script to other users. It is best to encode messages on the receiving clients rather than the server, because your SignalR application may have many different types of clients. Therefore, HTML-encoding works for a web client, but not for other types of clients. For example, a web client method to display a chat message would safely handle the user name and message by calling the `html()` function.

```
chat.client.addMessageToPage = function (name, message) {
    // Html encode display name and message.
    var encodedName = $('<div />').text(name).html();
    var encodedMsg = $('<div />').text(message).html();
    // Add the message to the page.
    $('#discussion').append('<li><strong>' + encodedName
        + '</strong>:  ' + encodedMsg + '</li>');
};
```

Reconciling a change in user status with an active connection

If a user's authentication status changes while an active connection exists, the user will receive an error that states, "The user identity cannot change during an active SignalR connection." In that case, your application should re-connect to the server to make sure the connection id and username are coordinated. For example, if your application allows the user to log out while an active connection exists, the username for the connection will no longer match the name that is passed in for the next request. You will want to stop the connection before the user logs out, and then restart it.

However, it is important to note that most applications will not need to manually stop and start the connection. If your application redirects users to a separate page after logging out, such as the default behavior in a Web Forms application or MVC application, or refreshes the current page after logging out, the active connection is

automatically disconnected and does not require any additional action.

The following example shows how to stop and start a connection when the user status has changed.

```
<script type="text/javascript">
    $(function () {
        var chat = $.connection.sampleHub;
        $.connection.hub.start().done(function () {
            $('#logoutbutton').click(function () {
                chat.connection.stop();
                $.ajax({
                    url: "Services/SampleWebService.svc/LogOut",
                    type: "POST"
                }).done(function () {
                    chat.connection.start();
                });
            });
        });
    });
</script>
```

Or, the user's authentication status may change if your site uses sliding expiration with Forms Authentication, and there is no activity to keep the authentication cookie valid. In that case, the user will be logged out and the user name will no longer match the user name in the connection token. You can fix this problem by adding some script that periodically requests a resource on the web server to keep the authentication cookie valid. The following example shows how to request a resource every 30 minutes.

```
$(function () {
    setInterval(function() {
        $.ajax({
            url: "Ping.aspx",
            cache: false
        });
    }, 1800000);
});
```

Automatically generated JavaScript proxy files

If you do not want to include all of the hubs and methods in the JavaScript proxy file for each user, you can disable the automatic generation of the file. You might choose this option if you have multiple hubs and methods, but do not want every user to be aware of all of the methods. You disable automatic generation by setting `EnableJavaScriptProxies` to `false`.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableJavaScriptProxies = false;
RouteTable.Routes.MapHubs("/signalr", hubConfiguration);
```

For more information about the JavaScript proxy files, see The generated proxy and what it does for you.

Exceptions

You should avoid passing exception objects to clients because the objects may expose sensitive information to the clients. Instead, call a method on the client that displays the relevant error message.

```
public Task SampleMethod()
{
    try
    {
        // code that can throw an exception
    }
    catch(Exception e)
    {
        // add code to log exception and take remedial steps

        return Clients.Caller.DisplayError("Sorry, the request could not be processed.");
    }
}
```

Authentication and Authorization for SignalR Hubs (SignalR 1.x)

2/20/2020 • 7 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to restrict which users or roles can access hub methods.

Overview

This topic contains the following sections:

- Authorize attribute
- Require authentication for all hubs
- Customized authorization
- Pass authentication information to clients
- Authentication options for .NET clients
  - Cookie with Forms Authentication
  - Windows Authentication
  - Connection header
  - Certificate

Authorize attribute

SignalR provides the Authorize attribute to specify which users or roles have access to a hub or method. This attribute is located in the `Microsoft.AspNet.SignalR` namespace. You apply the `Authorize` attribute to either a hub or particular methods in a hub. When you apply the `Authorize` attribute to a hub class, the specified authorization requirement is applied to all of the methods in the hub. The different types of authorization requirements that you can apply are shown below. Without the `Authorize` attribute, all public methods on the hub are available to a client that is connected to the hub.

If you have defined a role named "Admin" in your web application, you could specify that only users in that role can access a hub with the following code.

```
[Authorize(Roles = "Admin")]
public class AdminAuthHub : Hub
{
}
```

Or, you can specify that a hub contains one method that is available to all users, and a second method that is only available to authenticated users, as shown below.

```
public class SampleHub : Hub
{
    public void UnrestrictedSend(string message){ . . . }

    [Authorize]
    public void AuthenticatedSend(string message){ . . . }
}
```

The following examples address different authorization scenarios:

- `[Authorize]` – only authenticated users
- `[Authorize(Roles = "Admin,Manager")]` – only authenticated users in the specified roles
- `[Authorize(Users = "user1,user2")]` – only authenticated users with the specified user names
- `[Authorize(RequireOutgoing=false)]` – only authenticated users can invoke the hub, but calls from the server back to clients are not limited by authorization, such as, when only certain users can send a message but all others can receive the message. The RequireOutgoing property can only be applied to the entire hub, not on individuals methods within the hub. When RequireOutgoing is not set to false, only users that meet the authorization requirement are called from the server.

Require authentication for all hubs

You can require authentication for all hubs and hub methods in your application by calling the RequireAuthentication method when the application starts. You might use this method when you have multiple hubs and want to enforce an authentication requirement for all of them. With this method, you cannot specify role, user, or outgoing authorization. You can only specify that access to the hub methods is restricted to authenticated users. However, you can still apply the Authorize attribute to hubs or methods to specify additional requirements. Any requirement you specify in attributes is applied in addition to the basic requirement of authentication.

The following example shows a Global.asax file which restricts all hub methods to authenticated users.

```
public class Global : HttpApplication
{
    void Application_Start(object sender, EventArgs e)
    {
        RouteTable.Routes.MapHubs();
        GlobalHost.HubPipeline.RequireAuthentication();
    }
}
```

If you call the `RequireAuthentication()` method after a SignalR request has been processed, SignalR will throw a `InvalidOperationException` exception. This exception is thrown because you cannot add a module to the HubPipeline after the pipeline has been invoked. The previous example shows calling the `RequireAuthentication` method in the `Application_Start` method which is executed one time prior to handling the first request.

Customized authorization

If you need to customize how authorization is determined, you can create a class that derives from `AuthorizeAttribute` and override the UserAuthorized method. This method is called for each request to determine whether the user is authorized to complete the request. In the overridden method, you provide the necessary logic for your authorization scenario. The following example shows how to enforce authorization through claims-based identity.

```
[AttributeUsage(AttributeTargets.Class, Inherited = false, AllowMultiple = false)]
public class AuthorizeClaimsAttribute : AuthorizeAttribute
{
    protected override bool UserAuthorized(System.Security.Principal.IPrincipal user)
    {
        if (user == null)
        {
            throw new ArgumentNullException("user");
        }

        var principal = (ClaimsPrincipal)user;

        if (principal != null)
        {
            Claim authenticated = principal.FindFirst(ClaimTypes.Authentication);
            return authenticated.Value == "true" ? true : false;
        }
        else
        {
            return false;
        }
    }
}
```

Pass authentication information to clients

You may need to use authentication information in the code that runs on the client. You pass the required information when calling the methods on the client. For example, a chat application method could pass as a parameter the user name of the person posting a message, as shown below.

```
public Task SendChatMessage(string message)
{
    string name;
    var user = Context.User;

    if (user.Identity.IsAuthenticated)
    {
        name = user.Identity.Name;
    }
    else
    {
        name = "anonymous";
    }
    return Clients.All.addMessageToPage(name, message);
}
```

Or, you can create an object to represent the authentication information and pass that object as a parameter, as shown below.

```
public class SampleHub : Hub
{
    public override Task OnConnected()
    {
        return Clients.All.joined(GetAuthInfo());
    }

    protected object GetAuthInfo()
    {
        var user = Context.User;
        return new
        {
            IsAuthenticated = user.Identity.IsAuthenticated,
            IsAdmin = user.IsInRole("Admin"),
            UserName = user.Identity.Name
        };
    }
}
```

You should never pass one client's connection id to other clients, as a malicious user could use it to mimic a request from that client.

Authentication options for .NET clients

When you have a .NET client, such as a console app, which interacts with a hub that is limited to authenticated users, you can pass the authentication credentials in a cookie, the connection header, or a certificate. The examples in this section show how to use those different methods for authenticating a user. They are not fully-functional SignalR apps. For more information about .NET clients with SignalR, see Hubs API Guide - .NET Client.

Cookie

When your .NET client interacts with a hub that uses ASP.NET Forms Authentication, you will need to manually set the authentication cookie on the connection. You add the cookie to the `CookieContainer` property on the HubConnection object. The following example shows a console app that retrieves an authentication cookie from a web page and adds that cookie to the connection. The URL `https://www.contoso.com/RemoteLogin` in the example points to a web page that you would need to create. The page would retrieve the posted user name and password, and attempt to log in the user with the credentials.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        Cookie returnedCookie;

        Console.Write("Enter user name: ");
        string username = Console.ReadLine();

        Console.Write("Enter password: ");
        string password = Console.ReadLine();

        var authResult = AuthenticateUser(username, password, out returnedCookie);

        if (authResult)
        {
            connection.CookieContainer = new CookieContainer();
            connection.CookieContainer.Add(returnedCookie);
            Console.WriteLine("Welcome " + username);
        }
        else
        {
            Console.WriteLine("Login failed");
        }
    }

    private static bool AuthenticateUser(string user, string password, out Cookie authCookie)
    {
        var request = WebRequest.Create("https://www.contoso.com/RemoteLogin") as HttpWebRequest;
        request.Method = "POST";
        request.ContentType = "application/x-www-form-urlencoded";
        request.CookieContainer = new CookieContainer();

        var authCredentials = "UserName=" + user + "&Password=" + password;
        byte[] bytes = System.Text.Encoding.UTF8.GetBytes(authCredentials);
        request.ContentLength = bytes.Length;
        using (var requestStream = request.GetRequestStream())
        {
            requestStream.Write(bytes, 0, bytes.Length);
        }

        using (var response = request.GetResponse() as HttpWebResponse)
        {
            authCookie = response.Cookies[FormsAuthentication.FormsCookieName];
        }

        if (authCookie != null)
        {
            return true;
        }
        else
        {
            return false;
        }
    }
}
```

The console app posts the credentials to www.contoso.com/RemoteLogin which could refer to an empty page that contains the following code-behind file.

```
using System;
using System.Web.Security;

namespace SignalRWithConsoleChat
{
    public partial class RemoteLogin : System.Web.UI.Page
    {
        protected void Page_Load(object sender, EventArgs e)
        {
            string username = Request["UserName"];
            string password = Request["Password"];
            bool result = Membership.ValidateUser(username, password);
            if (result)
            {
                FormsAuthentication.SetAuthCookie(username, false);
            }
        }
    }
}
```

Windows authentication

When using Windows authentication, you can pass the current user's credentials by using the DefaultCredentials property. You set the credentials for the connection to the value of the DefaultCredentials.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        connection.Credentials = CredentialCache.DefaultCredentials;
        connection.Start().Wait();
    }
}
```

Connection header

If your application is not using cookies, you can pass user information in the connection header. For example, you can pass a token in the connection header.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        connection.Headers.Add("myauthtoken", /* token data */);
        connection.Start().Wait();
    }
}
```

Then, in the hub, you would verify the user's token.

Certificate

You can pass a client certificate to verify the user. You add the certificate when creating the connection. The following example shows only how to add a client certificate to the connection; it does not show the full console app. It uses the X509Certificate class which provides several different ways to create the certificate.

```
class Program
{
    static void Main(string[] args)
    {
        var connection = new HubConnection("http://www.contoso.com/");
        connection.AddClientCertificate(X509Certificate.CreateFromCertFile("MyCert.cer"));
        connection.Start().Wait();
    }
}
```

Authentication and Authorization for SignalR Persistent Connections (SignalR 1.x)

2/20/2020 • 2 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to enforce authorization on a persistent connection. For general information about integrating security into a SignalR application, see Introduction to Security.

Enforce authorization

To enforce authorization rules when using a PersistentConnection you must override the `AuthorizeRequest` method. You cannot use the `Authorize` attribute with persistent connections. The `AuthorizeRequest` method is called by the SignalR Framework before every request to verify that the user is authorized to perform the requested action. The `AuthorizeRequest` method is not called from the client; instead, you authenticate the user through your application's standard authentication mechanism.

The example below shows how to limit requests to authenticated users.

```
public class AuthenticatedConnection : PersistentConnection
{
    protected override bool AuthorizeRequest(IRequest request)
    {
        return request.User.Identity.IsAuthenticated;
    }
}
```

You can add any customized authorization logic in the AuthorizeRequest method; such as, checking whether a user belongs to a particular role.

SignalR Performance (SignalR 1.x)

2/20/2020 • 8 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

> This topic describes how to design for, measure, and improve performance in a SignalR application.

For a recent presentation on SignalR performance and scaling, see Scaling the Real-time Web with ASP.NET SignalR.

This topic contains the following sections:

- Design considerations
- Tuning your SignalR server for performance
- Troubleshooting performance issues
- Using SignalR performance counters
- Using other performance counters
- Other resources

Design considerations

This section describes patterns that can be implemented during the design of a SignalR application, to ensure that performance is not being hindered by generating unnecessary network traffic.

Throttling message frequency

Even in an application that sends out messages at a high frequency (such as a realtime gaming application), most applications don't need to send more than a few messages a second. To reduce the amount of traffic that each client generates, a message loop can be implemented that queues and sends out messages no more frequently than a fixed rate (that is, up to a certain number of messages will be sent every second, if there are messages in that time interval to be sent). For a sample application that throttles messages to a certain rate (from both client and server), see High-Frequency Realtime with SignalR.

Reducing message size

You can reduce the size of a SignalR message by reducing the size of your serialized objects. In server code, if you're sending an object that contains properties that don't need to be transmitted, prevent those properties from being serialized by using the `JsonIgnore` attribute. The names of properties are also stored in the message; the names of properties can be shortened using the `JsonProperty` attribute. The following code sample demonstrates how to exclude a property from being sent to the client, and how to shorten property names:

.NET server code that demonstrates the JsonIgnore attribute to exclude data from being sent to the client, and the JsonProperty attribute to reduce message size

```
using Newtonsoft.Json;
using System;
public class ShapeModel
{
[JsonProperty("l")]
    public double Left { get; set; }
[JsonProperty("t")]
    public double Top { get; set; }
    // We don't want the client to get the "LastUpdatedBy" property
[JsonIgnore]
    public string LastUpdatedBy { get; set; }
}
```

In order to retain readability/ maintainability in the client code, the abbreviated property names can be remapped to human-friendly names after the message is received. The following code sample demonstrates one possible way of remapping shortened names to longer ones, by defining a message contract (mapping), and using the `reMap` function to apply the contract to the optimized message class:

Client-side JavaScript code that remaps shortened property names to human-readable names

```
function reMap(smallObject, contract) {
    var largeObject = {};
    for (var smallProperty in contract) {
        largeObject[contract[smallProperty]] = smallObject[smallProperty];
    }
    return largeObject;
}
var shapeModelContract = {
    l: "left",
    t: "top"
};
myHub.client.setShape = function (shapeModelSmall) {
    var shapeModel = reMap(shapeModelSmall, shapeModelContract);
    // shapeModelSmall has "l" and "t" properties  but after remapping
    // shapeModel now has "left" and "top" properties
};
```

Names can be shortened in messages from the client to the server as well, using the same method.

Reducing the memory footprint (that is, the amount of memory used for the message) of the message object can also improve performance. For example, if the full range of an `int` is not needed, a `short` or `byte` can be used instead.

Since messages are stored in the message bus in server memory, reducing the size of messages can also address server memory issues.

Tuning your SignalR server for performance

The following configuration settings can be used to tune your server for better performance in a SignalR application. For general information on how to improve performance in an ASP.NET application, see Improving ASP.NET Performance.

SignalR configuration settings

- **DefaultMessageBufferSize**: By default, SignalR retains 1000 messages in memory per hub per connection. If large messages are being used, this may create memory issues which can be alleviated by reducing this value. This setting can be set in the `Application_Start` event handler in an ASP.NET application, or in the `Configuration` method of an OWIN startup class in a self-hosted application. The following sample demonstrates how to reduce this value in order to reduce the memory footprint of your application in order to reduce the amount of server memory used:

.NET server code in Global.asax for decreasing default message buffer size

```
protected void Application_Start(object sender, EventArgs e)
{
    GlobalHost.Configuration.DefaultMessageBufferSize = 500;
}
```

IIS configuration settings

- **Max concurrent requests per application**: Increasing the number of concurrent IIS requests will increase server resources available for serving requests. The default value is 5000; to increase this setting, execute the following commands in an elevated command prompt:

```
cd %windir%\System32\inetsrv\
appcmd.exe set config /section:system.webserver/serverRuntime
        /appConcurrentRequestLimit:10000
```

ASP.NET configuration settings

This section includes configuration settings that can be set in the `aspnet.config` file. This file is found in one of two locations, depending on platform:

- `%windir%\Microsoft.NET\Framework\v4.0.30319\aspnet.config`
- `%windir%\Microsoft.NET\Framework64\v4.0.30319\aspnet.config`

ASP.NET settings that may improve SignalR performance include the following:

- **Maximum concurrent requests per CPU**: Increasing this setting may alleviate performance bottlenecks. To increase this setting, add the following configuration setting to the `aspnet.config` file:

```
<?xml version="1.0" encoding="UTF-8" ?>
<configuration>
    <system.web>
        <applicationPool maxConcurrentRequestsPerCPU="20000" />
    </system.web>
</configuration>
```

- **Request Queue Limit**: When the total number of connections exceeds the `maxConcurrentRequestsPerCPU` setting, ASP.NET will start throttling requests using a queue. To increase the size of the queue, you can increase the `requestQueueLimit` setting. To do this, add the following configuration setting to the `processModel` node in `config/machine.config` (rather than `aspnet.config`):

```
<processModel autoConfig="false" requestQueueLimit="250000" />
```

Troubleshooting performance issues

This section describes ways to find performance bottlenecks in your application.

Verifying that WebSocket is being used

While SignalR can use a variety of transports for communication between client and server, WebSocket offers a significant performance advantage, and should be used if the client and server support it. To determine if your client and server meet the requirements for WebSocket, see Transports and Fallbacks. To determine what transport is being used in your application, you can use the browser developer tools, and examine the logs to see what transport is being used for the connection. For information on using the browser development tools in Internet

Explorer and Chrome, see Transports and Fallbacks.

Using SignalR performance counters

This section describes how to enable and use SignalR performance counters, found in the `Microsoft.AspNet.SignalR.Utils` package.

Installing signalr.exe

Performance counters can be added to the server using a utility called SignalR.exe. To install this utility, follow these steps:

1. In Visual Studio, select **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution**
2. Search for **signalr.utils**, and select Install.

3. Accept the license agreement to install the package.
4. SignalR.exe will be installed to `<project folder>/packages/Microsoft.AspNet.SignalR.Utils.<version>/tools`.

Installing performance counters with SignalR.exe

To install SignalR performance counters, run SignalR.exe in an elevated command prompt with the following parameter:

```
SignalR.exe ipc
```

To remove SignalR performance counters, run SignalR.exe in an elevated command prompt with the following parameter:

```
SignalR.exe upc
```

SignalR Performance counters

The utilities package installs the following performance counters. The "Total" counters measure the number of events since the last application pool or server restart.

Connection metrics

The following metrics measure the connection lifetime events that occur. For more information, see Understanding and Handling Connection Lifetime Events.

- Connections Connected
- Connections Reconnected
- Connections Disconnected
- Connections Current

Message metrics

The following metrics measure the message traffic generated by SignalR.

- **Connection Messages Received Total**
- **Connection Messages Sent Total**
- **Connection Messages Received/Sec**
- **Connection Messages Sent/Sec**

Message bus metrics

The following metrics measure traffic through the internal SignalR message bus, the queue in which all incoming and outgoing SignalR messages are placed. A message is **Published** when it is sent or broadcast. A **Subscriber** in this context is a subscription on the message bus; this should equal the number of clients plus the server itself. An **Allocated Worker** is a component that sends data to active connections; a **Busy Worker** is one that is actively sending a message.

- **Message Bus Messages Received Total**
- **Message Bus Messages Received/Sec**
- **Message Bus Messages Published Total**
- **Message Bus Messages Published/Sec**
- **Message Bus Subscribers Current**
- **Message Bus Subscribers Total**
- **Message Bus Subscribers/Sec**
- **Message Bus Allocated Workers**
- **Message Bus Busy Workers**
- **Message Bus Topics Current**

Error metrics

The following metrics measure errors generated by SignalR message traffic. **Hub Resolution** errors occur when a hub or hub method cannot be resolved. **Hub Invocation** errors are exceptions thrown while invoking a hub method. **Transport** errors are connection errors thrown during an HTTP request or response.

- **Errors: All Total**
- **Errors: All/Sec**
- **Errors: Hub Resolution Total**
- **Errors: Hub Resolution/Sec**
- **Errors: Hub Invocation Total**
- **Errors: Hub Invocation/Sec**
- **Errors: Transport Total**
- **Errors: Transport/Sec**

Scaleout metrics

The following metrics measure traffic and errors generated by the scaleout provider. A **Stream** in this context is a scale unit used by the scaleout provider; this is a table if SQL Server is used, a Topic if Service Bus is used, and a Subscription if Redis is used. By default, only one stream is used, but this can be increased through configuration on SQL Server and Service Bus. A **Buffering** stream is one that has entered a faulted state; when the stream is in the faulted state, all messages sent to the backplane will fail immediately until the stream is no longer faulting. The **Send Queue Length** is the number of messages that have been posted but not yet sent.

- **Scaleout Message Bus Messages Received/Sec**
- **Scaleout Streams Total**
- **Scaleout Streams Open**
- **Scaleout Streams Buffering**
- **Scaleout Errors Total**

- **Scaleout Errors/Sec**
- **Scaleout Send Queue Length**

For more information on what these counters are measuring, see SignalR Scaleout with Azure Service Bus.

Using other performance counters

The following performance counters may also be useful in monitoring your application's performance.

Memory

- .NET CLR Memory# bytes in all Heaps (for w3wp)

ASP.NET

- ASP.NET\Requests Current
- ASP.NET\Queued
- ASP.NET\Rejected

CPU

- Processor Information\Processor Time

TCP/IP

- TCPv6/Connections Established
- TCPv4/Connections Established

Web Service

- Web Service\Current Connections
- Web Service\Maximum Connections

Threading

- .NET CLR LocksAndThreads# of current logical Threads
- .NET CLR LocksAnd Threads# of current physical Threads

Other Resources

For more information on ASP.NET performance monitoring and tuning, see the following topics:

- ASP.NET Performance Overview
- ASP.NET Thread Usage on IIS 7.5, IIS 7.0, and IIS 6.0
- <applicationPool> Element (Web Settings)

Introduction to Scaleout in SignalR 1.x

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

In general, there are two ways to scale a web application: *scale up* and *scale out*.

- Scale up means using a larger server (or a larger VM) with more RAM, CPUs, etc.
- Scale out means adding more servers to handle the load.

The problem with scaling up is that you quickly hit a limit on the size of the machine. Beyond that, you need to scale out. However, when you scale out, clients can get routed to different servers. A client that is connected to one server will not receive messages sent from another server.

One solution is to forward messages between servers, using a component called a *backplane*. With a backplane enabled, each application instance sends messages to the backplane, and the backplane forwards them to the other application instances. (In electronics, a backplane is a group of parallel connectors. By analogy, a SignalR backplane connects multiple servers.)

SignalR currently provides three backplanes:

- **Azure Service Bus**. Service Bus is a messaging infrastructure that allows components to send messages in a loosely coupled way.
- **Redis**. Redis is an in-memory key-value store. Redis supports a publish/subscribe ("pub/sub") pattern for sending messages.
- **SQL Server**. The SQL Server backplane writes messages to SQL tables. The backplane uses Service Broker for efficient messaging. However, it also works if Service Broker is not enabled.

If you deploy your application on Azure, consider using the Azure Service Bus backplane. If you are deploying to your own server farm, consider the SQL Server or Redis backplanes.

The following topics contain step-by-step tutorials for each backplane:

- SignalR Scaleout with Azure Service Bus
- SignalR Scaleout with Redis
- SignalR Scaleout with SQL Server

Implementation

In SignalR, every message is sent through a message bus. A message bus implements the IMessageBus interface, which provides a publish/subscribe abstraction. The backplanes work by replacing the default **IMessageBus** with a bus designed for that backplane. For example, the message bus for Redis is RedisMessageBus, and it uses the Redis pub/sub mechanism to send and receive messages.

Each server instance connects to the backplane through the bus. When a message is sent, it goes to the backplane, and the backplane sends it to every server. When a server gets a message from the backplane, it puts the message in its local cache. The server then delivers messages to clients from its local cache.

For each client connection, the client's progress in reading the message stream is tracked using a cursor. (A cursor represents a position in the message stream.) If a client disconnects and then reconnects, it asks the bus for any messages that arrived after the client's cursor value. The same thing happens when a connection uses long polling. After a long poll request completes, the client opens a new connection and asks for messages that arrived after the cursor.

The cursor mechanism works even if a client is routed to a different server on reconnect. The backplane is aware of all the servers, and it doesn't matter which server a client connects to.

Limitations

Using a backplane, the maximum message throughput is lower than it is when clients talk directly to a single server node. That's because the backplane forwards every message to every node, so the backplane can become a bottleneck. Whether this limitation is a problem depends on the application. For example, here are some typical SignalR scenarios:

- Server broadcast (e.g., stock ticker): Backplanes work well for this scenario, because the server controls the rate at which messages are sent.
- Client-to-client (e.g., chat): In this scenario, the backplane might be a bottleneck if the number of messages scales with the number of clients; that is, if the rate of messages grows proportionally as more clients join.
- High-frequency realtime (e.g., real-time games): A backplane is not recommended for this scenario.

Enabling Tracing For SignalR Scaleout

To enable tracing for the backplanes, add the following sections to the web.config file, under the root **configuration** element:

```
<configuration>
  <system.diagnostics>
    <sources>
      <source name="SignalR.SqlMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.ServiceBusMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.ScaleoutMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
    </sources>
    <switches>
      <add name="SignalRSwitch" value="Verbose" />
      <!-- Off, Critical, Error, Warning, Information, Verbose -->
    </switches>
    <sharedListeners>
      <add name="SignalR-Bus"
          type="System.Diagnostics.TextWriterTraceListener"
          initializeData="bus.log.txt" />
    </sharedListeners>
    <trace autoflush="true" />
  </system.diagnostics>
  . . .
</configuration>
```

SignalR Scaleout with Azure Service Bus (SignalR 1.x)

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

In this tutorial, you will deploy a SignalR application to a Windows Azure Web Role, using the Service Bus backplane to distribute messages to each role instance.

Prerequisites:

- A Windows Azure account.
- The Windows Azure SDK.
- Visual Studio 2012.

The service bus backplane is also compatible with Service Bus for Windows Server, version 1.1. However, it is not compatible with version 1.0 of Service Bus for Windows Server.

Pricing

The Service Bus backplane uses topics to send messages. For the latest pricing information, see Service Bus. At the time of this writing, you can send 1,000,000 messages per month for less than $1. The backplane sends a service bus message for each invocation of a SignalR hub method. There are also some control messages for connections, disconnections, joining or leaving groups, and so forth. In most applications, the majority of the message traffic will be hub method invocations.

Overview

Before we get to the detailed tutorial, here is a quick overview of what you will do.

1. Use the Windows Azure portal to create a new Service Bus namespace.
2. Add these NuGet packages to your application:
   - Microsoft.AspNet.SignalR

- Microsoft.AspNet.SignalR.ServiceBus

3. Create a SignalR application.

4. Add the following code to Global.asax to configure the backplane:

```
protected void Application_Start()
{
    string connectionString = "Service Bus connection string";
    GlobalHost.DependencyResolver.UseServiceBus(connectionString, "YourAppName");

    RouteTable.Routes.MapHubs();
    // ...
}
```

For each application, pick a different value for "YourAppName". Do not use the same value across multiple applications.

Create the Azure Services

Create a Cloud Service, as described in How to Create and Deploy a Cloud Service. Follow the steps in the section "How to: Create a cloud service using Quick Create". For this tutorial, you do not need to upload a certificate.

Create a new Service Bus namespace, as described in How to Use Service Bus Topics/Subscriptions. Follow the steps in the section "Create a Service Namespace".

> **NOTE**
>
> Make sure to select the same region for the cloud service and the Service Bus namespace.

Create the Visual Studio Project

Start Visual Studio. From the **File** menu, click **New Project**.

In the **New Project** dialog box, expand **Visual C#**. Under **Installed Templates**, select **Cloud** and then select **Windows Azure Cloud Service**. Keep the default .NET Framework 4.5. Name the application ChatService and click **OK**.

In the **New Windows Azure Cloud Service** dialog, select ASP.NET MVC 4 Web Role. Click the right-arrow button (>) to add the role to your solution.

Hover the mouse over the new role, so the pencil icon visible. Click this icon to rename the role. Name the role "SignalRChat" and click **OK**.

In the **New ASP.NET MVC 4 Project** wizard, select **Internet Application**. Click **OK**. The project wizard creates two projects:

- ChatService: This project is the Windows Azure application. It defines the Azure roles and other configuration options.

- SignalRChat: This project is your ASP.NET MVC 4 project.

Create the SignalR Chat Application

To create the chat application, follow the steps in the tutorial Getting Started with SignalR and MVC 4.

Use NuGet to install the required libraries. From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the **Package Manager Console** window, enter the following commands:

```
Install-Package -ProjectName SignalRChat Microsoft.AspNet.SignalR
Install-Package -ProjectName SignalRChat Microsoft.AspNet.SignalR.ServiceBus
```

Use the `-ProjectName` option to install the packages to the ASP.NET MVC project, rather than the Windows Azure project.

Configure the Backplane

In your application's Global.asax file, add the following code:

```
protected void Application_Start()
{
    string connectionString = "";
    GlobalHost.DependencyResolver.UseServiceBus(connectionString, "Chat");

    RouteTable.Routes.MapHubs();
}
```

Now you need to get your service bus connection string. In the Azure portal, select the service bus namespace that you created and click the Access Key icon.

Copy the connection string to the clipboard, then paste it into the *connectionString* variable.

```
string connectionString = "Endpoint=sb://xxxx.servicebus.windows.net/;
SharedSecretIssuer=owner;SharedSecretValue=XXXXXXXX";
```

Deploy to Azure

In Solution Explorer, expand the **Roles** folder inside the ChatService project.

Right-click the SignalRChat role and select **Properties**. Select the **Configuration** tab. Under **Instances** select 2. You can also set the VM size to **Extra Small**.

Save the changes.

In Solution Explorer, right-click the ChatService project. Select **Publish**.

If this is your first time publishing to Windows Azure, you must download your credentials. In the **Publish** wizard, click "Sign in to download credentials". This will prompt you to sign into the Windows Azure portal and download a publish settings file.

Click **Import** and select the publish settings file that you downloaded.

Click **Next**. In the **Publish Settings** dialog, under **Cloud Service**, select the cloud service that you created earlier.

Click **Publish**. It can take a few minutes to deploy the application and start the VMs.

Now when you run the chat application, the role instances communicate through Azure Service Bus, using a Service Bus topic. A topic is a message queue that allows multiple subscribers.

The backplane automatically creates the topic and the subscriptions. To see the subscriptions and message activity, open the Azure portal, select the Service Bus namespace, and click on "Topics".

ALL QUEUES TOPICS RELAYS NOTIFICATION HUBS PREVIEW

NAME	STATUS	CURRENT SIZE	MAX SIZE	SUBSCRIPTIONS
signalr_topic_chat_0	Active	0 B	1 GB	2

It make take a few minutes for the message activity to show up in the dashboard.

SignalR manages the topic lifetime. As long as your application is deployed, don't try to manually delete topics or change settings on the topic.

SignalR Scaleout with Redis (SignalR 1.x)

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

In this tutorial, you will use Redis to distribute messages across a SignalR application that is deployed on two separate IIS instances.

Redis is an in-memory key-value store. It also supports a messaging system with a publish/subscribe model. The SignalR Redis backplane uses the pub/sub feature to forward messages to other servers.

For this tutorial, you will use three servers:

- Two servers running Windows, which you will use to deploy a SignalR application.
- One server running Linux, which you will use to run Redis. For the screenshots in this tutorial, I used Ubuntu 12.04 TLS.

If you don't have three physical servers to use, you can create VMs on Hyper-V. Another option is to create VMs on Azure.

Although this tutorial uses the official Redis implementation, there is also a Windows port of Redis from MSOpenTech. Setup and configuration are different, but otherwise the steps are the same.

NOTE

SignalR scaleout with Redis does not support Redis clusters.

Overview

Before we get to the detailed tutorial, here is a quick overview of what you will do.

1. Install Redis and start the Redis server.
2. Add these NuGet packages to your application:

- Microsoft.AspNet.SignalR
- Microsoft.AspNet.SignalR.Redis

3. Create a SignalR application.

4. Add the following code to Global.asax to configure the backplane:

```
protected void Application_Start()
{
    GlobalHost.DependencyResolver.UseRedis("server", port, "password", "AppName");

    RouteTable.Routes.MapHubs();
    // ...
}
```

Ubuntu on Hyper-V

Using Windows Hyper-V, you can easily create an Ubuntu VM on Windows Server.

Download the Ubuntu ISO from http://www.ubuntu.com.

In Hyper-V, add a new VM. In the **Connect Virtual Hard Disk** step, select **Create a virtual hard disk**.

In the **Installation Options** step, select **Image file (.iso)**, click **Browse**, and browse to the Ubuntu installation ISO.

Install Redis

Follow the steps at http://redis.io/download to download and build Redis.

```
wget http://redis.googlecode.com/files/redis-2.6.12.tar.gz
tar xzf redis-2.6.12.tar.gz
cd redis-2.6.12
make
```

This builds the Redis binaries in the `src` directory.

By default, Redis does not require a password. To set a password, edit the `redis.conf` file, which is located in the root directory of the source code. (Make a backup copy of the file before you edit it!) Add the following directive to `redis.conf`:

```
requirepass YourStrongPassword1234
```

Now start the Redis server:

```
src/redis-server redis.conf
```

Open port 6379, which is the default port that Redis listens on. (You can change the port number in the configuration file.)

Create the SignalR Application

Create a SignalR application by following either of these tutorials:

- Getting Started with SignalR
- Getting Started with SignalR and MVC 4

Next, we'll modify the chat application to support scaleout with Redis. First, add the SignalR.Redis NuGet package to your project. In Visual Studio, from the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.AspNet.SignalR.Redis
```

Next, open the Global.asax file. Add the following code to the **Application_Start** method:

```
protected void Application_Start()
{
    GlobalHost.DependencyResolver.UseRedis("server", port, "password", "AppName");

    RouteTable.Routes.MapHubs();
}
```

- "server" is the name of the server that is running Redis.
- *port* is the port number
- "password" is the password that you defined in the redis.conf file.
- "AppName" is any string. SignalR creates a Redis pub/sub channel with this name.

For example:

```
GlobalHost.DependencyResolver.UseRedis("redis-server.cloudapp.net", 6379,
    "MyStrongPassword1234", "ChatApp");
```

Deploy and Run the Application

Prepare your Windows Server instances to deploy the SignalR application.

Add the IIS role. Include "Application Development" features, including the WebSocket Protocol.

Also include the Management Service (listed under "Management Tools").

Install Web Deploy 3.0. When you run IIS Manager, it will prompt you to install Microsoft Web Platform, or you can download the installer. In the Platform Installer, search for Web Deploy and install Web Deploy 3.0

Check that the Web Management Service is running. If not, start the service. (If you don't see Web Management Service in the list of Windows services, make sure that you installed the Management Service when you added the IIS role.)

By default, the Web Management Service listens on TCP port 8172. In Windows Firewall, create a new inbound rule to allow TCP traffic on port 8172. For more information, see Configuring Firewall Rules. (If you are hosting the VMs on Azure, you can do this directly in the Azure portal. See How to Set Up Endpoints to a Virtual Machine.)

Now you are ready to deploy the Visual Studio project from your development machine to the server. In Solution Explorer, right-click the solution and click **Publish**.

For more detailed documentation about web deployment, see Web Deployment Content Map for Visual Studio and ASP.NET.

If you deploy the application to two servers, you can open each instance in a separate browser window and see that they each receive SignalR messages from the other. (Of course, in a production environment, the two servers would sit behind a load balancer.)

If you're curious to see the messages that are sent to Redis, you can use the **redis-cli** client, which installs with Redis.

```
redis-cli -a password
SUBSCRIBE ChatApp
```

azureuser@mike-ubuntu: ~/redis-2.6.12/src

```
azureuser@mike-ubuntu:~/redis-2.6.12/src$ ./redis-cli
redis 127.0.0.1:6379> SUBSCRIBE ChatApp
Reading messages... (press Ctrl-C to quit)
1) "subscribe"
2) "ChatApp"
3) (integer) 1
1) "message"
2) "ChatApp"
3) "$\x00\x00\x00\x00\x00\x00\x00\x01\x00\x00\x00$1f3a95bf-3bde-4339-bee6-95e2a7
e51a88\th-ChatHub6\x00\x00\x00{\"H\":\"ChatHub\",\"M\":\"addMessage\",\"A\":[\"A
lice\",\"Hello\"]}\x00\x00\x00\x00"
1) "message"
2) "ChatApp"
3) "%\x00\x00\x00\x00\x00\x00\x00\x01\x00\x00\x00$e52a3a87-5e1c-4927-8b82-68ea47
d84a3c\th-ChatHub1\x00\x00\x00{\"H\":\"ChatHub\",\"M\":\"addMessage\",\"A\":[\"B
ob\",\"Hi\"]}\x00\x00\x00\x00"
```

SignalR Scaleout with SQL Server (SignalR 1.x)

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

In this tutorial, you will use SQL Server to distribute messages across a SignalR application that is deployed in two separate IIS instances. You can also run this tutorial on a single test machine, but to get the full effect, you need to deploy the SignalR application to two or more servers. You must also install SQL Server on one of the servers, or on a separate dedicated server. Another option is to run the tutorial using VMs on Azure.

Prerequisites

Microsoft SQL Server 2005 or later. The backplane supports both desktop and server editions of SQL Server. It does not support SQL Server Compact Edition or Azure SQL Database. (If your application is hosted on Azure, consider the Service Bus backplane instead.)

Overview

Before we get to the detailed tutorial, here is a quick overview of what you will do.

1. Create a new empty database. The backplane will create the necessary tables in this database.
2. Add these NuGet packages to your application:
   - Microsoft.AspNet.SignalR
   - Microsoft.AspNet.SignalR.SqlServer
3. Create a SignalR application.
4. Add the following code to Global.asax to configure the backplane:

```
protected void Application_Start()
{
    string sqlConnectionString = "Connecton string to your SQL DB";
    GlobalHost.DependencyResolver.UseSqlServer(sqlConnectionString);

    RouteTable.Routes.MapHubs();
    // ...
}
```

Configure the Database

Decide whether the application will use Windows authentication or SQL Server authentication to access the database. Regardless, make sure the database user has permissions to log in, create schemas, and create tables.

Create a new database for the backplane to use. You can give the database any name. You don't need to create any tables in the database; the backplane will create the necessary tables.

Enable Service Broker

It is recommended to enable Service Broker for the backplane database. Service Broker provides native support for messaging and queuing in SQL Server, which lets the backplane receive updates more efficiently. (However, the backplane also works without Service Broker.)

To check whether Service Broker is enabled, query the **is_broker_enabled** column in the **sys.databases** catalog view.

```
SELECT [name], [service_broker_guid], [is_broker_enabled]
FROM [master].[sys].[databases]
```

To enable Service Broker, use the following SQL query:

```
ALTER DATABASE YOUR_DATABASE SET ENABLE_BROKER
```

> **NOTE**
> If this query appears to deadlock, make sure there are no applications connected to the DB.

If you have enabled tracing, the traces will also show whether Service Broker is enabled.

Create a SignalR Application

Create a SignalR application by following either of these tutorials:

- Getting Started with SignalR
- Getting Started with SignalR and MVC 4

Next, we'll modify the chat application to support scaleout with SQL Server. First, add the SignalR.SqlServer NuGet package to your project. In Visual Studio, from the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.AspNet.SignalR.SqlServer
```

Next, open the Global.asax file. Add the following code to the **Application_Start** method:

```
protected void Application_Start()
{
    string sqlConnectionString = "<add your SQL connection string here>";
    GlobalHost.DependencyResolver.UseSqlServer(sqlConnectionString);

    RouteTable.Routes.MapHubs();
}
```

Deploy and Run the Application

Prepare your Windows Server instances to deploy the SignalR application.

Add the IIS role. Include "Application Development" features, including the WebSocket Protocol.

Also include the Management Service (listed under "Management Tools").

Install Web Deploy 3.0. When you run IIS Manager, it will prompt you to install Microsoft Web Platform, or you can download the installer. In the Platform Installer, search for Web Deploy and install Web Deploy 3.0

Check that the Web Management Service is running. If not, start the service. (If you don't see Web Management Service in the list of Windows services, make sure that you installed the Management Service when you added the IIS role.)

Finally, open port 8172 for TCP. This is the port that the Web Deploy tool uses.

Now you are ready to deploy the Visual Studio project from your development machine to the server. In Solution Explorer, right-click the solution and click **Publish**.

For more detailed documentation about web deployment, see Web Deployment Content Map for Visual Studio and ASP.NET.

If you deploy the application to two servers, you can open each instance in a separate browser window and see that they each receive SignalR messages from the other. (Of course, in a production environment, the two servers would sit behind a load balancer.)

After you run the application, you can see that SignalR has automatically created tables in the database:

SignalR manages the tables. As long as your application is deployed, don't delete rows, modify the table, and so forth.

SignalR Troubleshooting (SignalR 1.x)

4/17/2020 • 13 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document describes common troubleshooting issues with SignalR.

This document contains the following sections.

- Calling methods between the client and server silently fails
- Other connection issues
- Compilation and server-side errors
- Visual Studio issues
- Internet Information Services issues
- Azure issues

Calling methods between the client and server silently fails

This section describes possible causes for a method call between client and server to fail without a meaningful error message. In a SignalR application, the server has no information about the methods that the client implements; when the server invokes a client method, the method name and parameter data are sent to the client, and the method is executed only if it exists in the format that the server specified. If no matching method is found on the client, nothing happens, and no error message is raised on the server.

To further investigate client methods not getting called, you can turn on logging before calling the start method on the hub to see what calls are coming from the server. To enable logging in a JavaScript application, see How to enable client-side logging (JavaScript client version). To enable logging in a .NET client application, see How to enable client-side logging (.NET Client version).

Misspelled method, incorrect method signature, or incorrect hub name

If the name or signature of a called method does not exactly match an appropriate method on the client, the call will fail. Verify that the method name called by the server matches the name of the method on the client. Also, SignalR creates the hub proxy using camel-cased methods, as is appropriate in JavaScript, so a method called `SendMessage` on the server would be called `sendMessage` in the client proxy. If you use the `HubName` attribute in your server-side code, verify that the name used matches the name used to create the hub on the client. If you do not use the `HubName` attribute, verify that the name of the hub in a JavaScript client is camel-cased, such as chatHub instead of ChatHub.

Duplicate method name on client

Verify that you do not have a duplicate method on the client that differs only by case. If your client application has a method called `sendMessage`, verify that there isn't also a method called `SendMessage` as well.

Missing JSON parser on the client

SignalR requires a JSON parser to be present to serialize calls between the server and the client. If your client doesn't have a built-in JSON parser (such as Internet Explorer 7), you'll need to include one in your application. You

can download the JSON parser here.

Mixing Hub and PersistentConnection syntax

SignalR uses two communication models: Hubs and PersistentConnections. The syntax for calling these two communication models is different in the client code. If you have added a hub in your server code, verify that all of your client code uses the proper hub syntax.

JavaScript client code that creates a PersistentConnection in a JavaScript client

```
var myConnection = $.connection('/echo');
```

JavaScript client code that creates a Hub Proxy in a Javascript client

```
var myHub = $.connection.MyHub;
```

C# server code that maps a route to a PersistentConnection

```
RouteTable.Routes.MapConnection<MyConnection>("my", "/echo");
```

C# server code that maps a route to a Hub, or to multiple hubs if you have multiple applications

```
RouteTable.Routes.MapHubs();
```

Connection started before subscriptions are added

If the Hub's connection is started before methods that can be called from the server are added to the proxy, messages will not be received. The following JavaScript code will not start the hub properly:

Incorrect JavaScript client code that will not allow Hubs messages to be received

```
var chat = $.connection.chatHub;
$.connection.hub.start().done(function () {
    chat.client.broadcastMessage = function (name, message) {...};
});
```

Instead, add the method subscriptions before calling Start:

JavaScript client code that correctly adds subscriptions to a hub

```
var chat = $.connection.chatHub;
chat.client.broadcastMessage = function (name, message) {...};
    $.connection.hub.start().done(function () {
        ...
    });
```

Missing method name on the hub proxy

Verify that the method defined on the server is subscribed to on the client. Even though the server defines the method, it must still be added to the client proxy. Methods can be added to the client proxy in the following ways (Note that the method is added to the `client` member of the hub, not the hub directly):

JavaScript client code that adds methods to a hub proxy

```
// Method added to proxy in JavaScript:
myHubProxy.server.method1 = function (param1, param2) {...};
//Multiple methods added to proxy in JavaScript using jQuery:
$.extend(myHubProxy.server, {
    method1: function (param1, param2) {...},
    method2: function (param3, param4) {...}
});
```

Hub or hub methods not declared as Public

To be visible on the client, the hub implementation and methods must be declared as `public`.

Accessing hub from a different application

SignalR Hubs can only be accessed through applications that implement SignalR clients. SignalR cannot interoperate with other communication libraries (like SOAP or WCF web services.) If there is no SignalR client available for your target platform, you cannot access the server's endpoint directly.

Manually serializing data

SignalR will automatically use JSON to serialize your method parameters- there's no need to do it yourself.

Remote Hub method not executed on client in OnDisconnected function

This behavior is by design. When `OnDisconnected` is called, the hub has already entered the `Disconnected` state, which does not allow further hub methods to be called.

C# server code that correctly executes code in the OnDisconnected event

```
public class MyHub : Hub
{
    public override Task OnDisconnected()
    {
        // Do what you want here
        return base.OnDisconnected();
    }
}
```

Connection limit reached

When using the full version of IIS on a client operating system like Windows 7, a 10-connection limit is imposed. When using a client OS, use IIS Express instead to avoid this limit.

Cross-domain connection not set up properly

If a cross-domain connection (a connection for which the SignalR URL is not in the same domain as the hosting page) is not set up correctly, the connection may fail without an error message. For information on how to enable cross-domain communication, see How to establish a cross-domain connection.

Connection using NTLM (Active Directory) not working in .NET client

A connection in a .NET client application that uses Domain security may fail if the connection is not configured properly. To use SignalR in a domain environment, set the requisite connection property as follows:

C# client code that implements connection credentials

```
connection.Credentials = CredentialCache.DefaultCredentials;
```

Other connection issues

This section describes the causes and solutions for specific symptoms or error messages that occur during a connection.

"Start must be called before data can be sent" error

This error is commonly seen if code references SignalR objects before the connection is started. The wireup for handlers and the like that will call methods defined on the server must be added after the connection completes. Note that the call to `Start` is asynchronous, so code after the call may be executed before it completes. The best way to add handlers after a connection starts completely is to put them into a callback function that is passed as a parameter to the start method:

JavaScript client code that correctly adds event handlers that reference SignalR objects

```
$.connection.hub.start().done(function () {
    // Wire up Send button to call NewContosoChatMessage on the server.
    $('#newContosoChatMessage').click(function () {
        contosoChatHubProxy.server.newContosoChatMessage(
            $('#displayname').val(), $('#message').val());
            $('#message').val('').focus();
    });
```

This error will also be seen if a connection stops while SignalR objects are still being referenced.

"301 Moved Permanently" or "302 Moved Temporarily" error

This error may be seen if the project contains a folder called SignalR, which will interfere with the automatically-created proxy. To avoid this error, do not use a folder called `SignalR` in your application, or turn automatic proxy generation off. See The Generated Proxy and what it does for you for more details.

"403 Forbidden" error in .NET or Silverlight client

This error may occur in cross-domain environments where cross-domain communication is not properly enabled. For information on how to enable cross-domain communication, see How to establish a cross-domain connection. To establish a cross-domain connection in a Silverlight client, see Cross-domain connections from Silverlight clients.

"404 Not Found" error

There are several causes for this issue. Verify all of the following:

- **Hub proxy address reference not formatted correctly:** This error is commonly seen if the reference to the generated hub proxy address is not formatted correctly. Verify that the reference to the hub address is made properly. See How to reference the dynamically generated proxy for details.
- **Adding routes to application before adding the hub route:** If your application uses other routes, verify that the first route added is the call to `MapHubs`.

"500 Internal Server Error"

This is a very generic error that could have a wide variety of causes. The details of the error should appear in the server's event log, or can be found through debugging the server. More detailed error information may be obtained by turning on detailed errors on the server. For more information, see How to handle errors in the Hub class.

"TypeError: <hubType> is undefined" error

This error will result if the call to `MapHubs` is not made properly. See How to register the SignalR route and configure SignalR options for more information.

JsonSerializationException was unhandled by user code

Verify that the parameters you send to your methods do not include non-serializable types (like file handles or database connections). If you need to use members on a server-side object that you don't want to be sent to the client (either for security or for reasons of serialization), use the `JSONIgnore` attribute.

"Protocol error: Unknown transport" error

This error may occur if the client does not support the transports that SignalR uses. See Transports and Fallbacks for information on which browsers can be used with SignalR.

"JavaScript Hub proxy generation has been disabled."

This error will occur if `DisableJavaScriptProxies` is set while also including a reference to the dynamically generated proxy at `signalr/hubs`. For more information on creating the proxy manually, see The generated proxy and what it does for you.

"The connection ID is in the incorrect format" or "The user identity cannot change during an active SignalR connection" error

This error may be seen if authentication is being used, and the client is logged out before the connection is stopped. The solution is to stop the SignalR connection before logging the client out.

"Uncaught Error: SignalR: jQuery not found. Please ensure jQuery is referenced before the SignalR.js file" error

The SignalR JavaScript client requires jQuery to run. Verify that your reference to jQuery is correct, that the path used is valid, and that the reference to jQuery is before the reference to SignalR.

"Uncaught TypeError: Cannot read property '<property>' of undefined" error

This error results from not having jQuery or the hubs proxy referenced properly. Verify that your reference to jQuery and the hubs proxy is correct, that the path used is valid, and that the reference to jQuery is before the reference to the hubs proxy. The default reference to the hubs proxy should look like the following:

HTML client-side code that correctly references the Hubs proxy

```
<script src="/signalr/hubs"></script>
```

"RuntimeBinderException was unhandled by user code" error

This error may occur when the incorrect overload of `Hub.On` is used. If the method has a return value, the return type must be specified as a generic type parameter:

Method defined on the client (without generated proxy)

```
MyHub.On<ReturnType>("MethodName", LocalMethod);
```

Connection ID is inconsistent or connection breaks between page loads

This behavior is by design. Since the hub object is hosted in the page object, the hub is destroyed when the page refreshes. A multi-page application needs to maintain the association between users and connection IDs so that they will be consistent between page loads. The connection IDs can be stored on the server in either a `ConcurrentDictionary` object or a database.

"Value cannot be null" error

Server-side methods with optional parameters are not currently supported; if the optional parameter is omitted, the method will fail. For more information, see Optional Parameters.

"Firefox can't establish a connection to the server at <address>" error in Firebug

This error message can be seen in Firebug if negotiation of the WebSocket transport fails and another transport is used instead. This behavior is by design.

"The remote certificate is invalid according to the validation procedure" error in .NET client application

If your server requires custom client certificates, then you can add an x509certificate to the connection before the request is made. Add the certificate to the connection using `Connection.AddClientCertificate`.

Connection drops after authentication times out

This behavior is by design. Authentication credentials cannot be modified while a connection is active; to refresh credentials, the connection must be stopped and restarted.

OnConnected gets called twice when using jQuery Mobile

jQuery Mobile's `initializePage` function forces the scripts in each page to be re-executed, thus creating a second connection. Solutions for this issue include:

- Include the reference to jQuery Mobile before your JavaScript file.
- Disable the `initializePage` function by setting `$.mobile.autoInitializePage = false`.
- Wait for the page to finish initializing before starting the connection.

Messages are delayed in Silverlight applications using Server Sent Events

Messages are delayed when using server sent events on Silverlight. To force long polling to be used instead, use the following when starting the connection:

```
connection.Start(new LongPollingTransport());
```

"Permission Denied" using Forever Frame protocol

This is a known issue, described here. This symptom may be seen using the latest JQuery library; the workaround is to downgrade your application to JQuery 1.8.2.

Compilation and server-side errors

The following section contains possible solutions to compiler and server-side runtime errors.

Reference to Hub instance is null

Since a hub instance is created for each connection, you can't create an instance of a hub in your code yourself. To call methods on a hub from outside the hub itself, see How to call client methods and manage groups from outside the Hub class for how to obtain a reference to the hub context.

HTTPContext.Current.Session is null

This behavior is by design. SignalR does not support the ASP.NET session state, since enabling the session state would break duplex messaging.

No suitable method to override

You may see this error if you are using code from older documentation or blogs. Verify that you are not referencing names of methods that have been changed or deprecated (like `OnConnectedAsync`).

HostContextExtensions.WebSocketServerUrl is null

This behavior is by design. This member is deprecated and should not be used.

"A route named 'signalr.hubs' is already in the route collection" error

This error will be seen if `MapHubs` is called twice by your application. Some example applications call `MapHubs` directly in the global application file; others make the call in a wrapper class. Ensure that your application does not do both.

Visual Studio issues

This section describes issues encountered in Visual Studio.

Script Documents node does not appear in Solution Explorer

Some of our tutorials direct you to the "Script Documents" node in Solution Explorer while debugging. This node is produced by the JavaScript debugger, and will only appear while debugging browser clients in Internet Explorer; the node will not appear if Chrome or Firefox are used. The JavaScript debugger will also not run if another client

debugger is running, such as the Silverlight debugger.

SignalR does not work on Visual Studio 2008 or earlier

This behavior is by design. SignalR requires .NET Framework 4 or later; this requires that SignalR applications be developed in Visual Studio 2010 or later.

IIS issues

This section contains issues with Internet Information Services.

Web site crashes after MapHubs call

This issue has been fixed in the latest version of SignalR. Verify that you are using the latest released version of SignalR by updating your installation using NuGet.

Azure issues

This section contains issues with Microsoft Azure.

Messages are not received through the Azure backplane after altering topic names

The topics used by the Azure backplane are not intended to be user-configurable.

Dependency Injection in SignalR 1.x

2/20/2020 • 8 minutes to read • Edit Online

by Mike Wasson, Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Dependency injection is a way to remove hard-coded dependencies between objects, making it easier to replace an object's dependencies, either for testing (using mock objects) or to change run-time behavior. This tutorial shows how to perform dependency injection on SignalR hubs. It also shows how to use IoC containers with SignalR. An IoC container is a general framework for dependency injection.

What is Dependency Injection?

Skip this section if you are already familiar with dependency injection.

Dependency injection (DI) is a pattern where objects are not responsible for creating their own dependencies. Here is a simple example to motivate DI. Suppose you have an object that needs to log messages. You might define a logging interface:

```
interface ILogger
{
    void LogMessage(string message);
}
```

In your object, you can create an `ILogger` to log messages:

```
// Without dependency injection.
class SomeComponent
{
    ILogger _logger = new FileLogger(@"C:\logs\log.txt");

    public void DoSomething()
    {
        _logger.LogMessage("DoSomething");
    }
}
```

This works, but it's not the best design. If you want to replace `FileLogger` with another `ILogger` implementation, you will have to modify `SomeComponent`. Supposing that a lot of other objects use `FileLogger`, you will need to change all of them. Or if you decide to make `FileLogger` a singleton, you'll also need to make changes throughout the application.

A better approach is to "inject" an `ILogger` into the object—for example, by using a constructor argument:

```
// With dependency injection.
class SomeComponent
{
    ILogger _logger;

    // Inject ILogger into the object.
    public SomeComponent(ILogger logger)
    {
        if (logger == null)
        {
            throw new NullReferenceException("logger");
        }
        _logger = logger;
    }

    public void DoSomething()
    {
        _logger.LogMessage("DoSomething");
    }
}
```

Now the object is not responsible for selecting which `ILogger` to use. You can switch `ILogger` implementations without changing the objects that depend on it.

```
var logger = new TraceLogger(@"C:\logs\log.etl");
var someComponent = new SomeComponent(logger);
```

This pattern is called constructor injection. Another pattern is setter injection, where you set the dependency through a setter method or property.

Simple Dependency Injection in SignalR

Consider the Chat application from the tutorial Getting Started with SignalR. Here is the hub class from that application:

```
public class ChatHub : Hub
{
    public void Send(string name, string message)
    {
        Clients.All.addMessage(name, message);
    }
}
```

Suppose that you want to store chat messages on the server before sending them. You might define an interface that abstracts this functionality, and use DI to inject the interface into the `ChatHub` class.

```
public interface IChatRepository
{
    void Add(string name, string message);
    // Other methods not shown.
}

public class ChatHub : Hub
{
    private IChatRepository _repository;

    public ChatHub(IChatRepository repository)
    {
        _repository = repository;
    }

    public void Send(string name, string message)
    {
        _repository.Add(name, message);
        Clients.All.addMessage(name, message);
    }
```

The only problem is that a SignalR application does not directly create hubs; SignalR creates them for you. By default, SignalR expects a hub class to have a parameterless constructor. However, you can easily register a function to create hub instances, and use this function to perform DI. Register the function by calling **GlobalHost.DependencyResolver.Register**.

```
protected void Application_Start()
{
    GlobalHost.DependencyResolver.Register(
        typeof(ChatHub),
        () => new ChatHub(new ChatMessageRepository()));

    RouteTable.Routes.MapHubs();

    // ...
}
```

Now SignalR will invoke this anonymous function whenever it needs to create a `ChatHub` instance.

IoC Containers

The previous code is fine for simple cases. But you still had to write this:

```
... new ChatHub(new ChatMessageRepository()) ...
```

In a complex application with many dependencies, you might need to write a lot of this "wiring" code. This code can be hard to maintain, especially if dependencies are nested. It is also hard to unit test.

One solution is to use an IoC container. An IoC container is a software component that is responsible for managing dependencies.You register types with the container, and then use the container to create objects. The container automatically figures out the dependency relations. Many IoC containers also allow you to control things like object lifetime and scope.

> **NOTE**
> "IoC" stands for "inversion of control", which is a general pattern where a framework calls into application code. An IoC container constructs your objects for you, which "inverts" the usual flow of control.

Using IoC Containers in SignalR

The Chat application is probably too simple to benefit from an IoC container. Instead, let's look at the StockTicker sample.

The StockTicker sample defines two main classes:

- `StockTickerHub`: The hub class, which manages client connections.
- `StockTicker`: A singleton that holds stock prices and periodically updates them.

`StockTickerHub` holds a reference to the `StockTicker` singleton, while `StockTicker` holds a reference to the **IHubConnectionContext** for the `StockTickerHub`. It uses this interface to communicate with `StockTickerHub` instances. (For more information, see Server Broadcast with ASP.NET SignalR.)

We can use an IoC container to untangle these dependencies a bit. First, let's simplify the `StockTickerHub` and `StockTicker` classes. In the following code, I've commented out the parts that we don't need.

Remove the parameterless constructor from `StockTicker`. Instead, we will always use DI to create the hub.

```
[HubName("stockTicker")]
public class StockTickerHub : Hub
{
    private readonly StockTicker _stockTicker;

    //public StockTickerHub() : this(StockTicker.Instance) { }

    public StockTickerHub(StockTicker stockTicker)
    {
        if (stockTicker == null)
        {
            throw new ArgumentNullException("stockTicker");
        }
        _stockTicker = stockTicker;
    }

    // ...
```

For StockTicker, remove the singleton instance. Later, we'll use the IoC container to control the StockTicker lifetime. Also, make the constructor public.

```
public class StockTicker
{
    //private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(
    //    () => new StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));

    // Important! Make this constructor public.
    public StockTicker(IHubConnectionContext clients)
    {
        if (clients == null)
        {
            throw new ArgumentNullException("clients");
        }

        Clients = clients;
        LoadDefaultStocks();
    }

    //public static StockTicker Instance
    //{
    //    get
    //    {
    //        return _instance.Value;
    //    }
    //}
```

Next, we can refactor the code by creating an interface for `StockTicker`. We'll use this interface to decouple the `StockTickerHub` from the `StockTicker` class.

Visual Studio makes this kind of refactoring easy. Open the file StockTicker.cs, right-click on the `StockTicker` class declaration, and select **Refactor** ... **Extract Interface**.

In the **Extract Interface** dialog, click **Select All**. Leave the other defaults. Click **OK**.

Visual Studio creates a new interface named `IStockTicker`, and also changes `StockTicker` to derive from `IStockTicker`.

Open the file IStockTicker.cs and change the interface to **public**.

```
public interface IStockTicker
{
    void CloseMarket();
    IEnumerable<Stock> GetAllStocks();
    MarketState MarketState { get; }
    void OpenMarket();
    void Reset();
}
```

In the `StockTickerHub` class, change the two instances of `StockTicker` to `IStockTicker`:

```
[HubName("stockTicker")]
public class StockTickerHub : Hub
{
    private readonly IStockTicker _stockTicker;

    public StockTickerHub(IStockTicker stockTicker)
    {
        if (stockTicker == null)
        {
            throw new ArgumentNullException("stockTicker");
        }
        _stockTicker = stockTicker;
    }
```

Creating an `IStockTicker` interface isn't strictly necessary, but I wanted to show how DI can help to reduce coupling between components in your application.

Add the Ninject Library

There are many open-source IoC containers for .NET. For this tutorial, I'll use Ninject. (Other popular libraries include Castle Windsor, Spring.Net, Autofac, Unity, and StructureMap.)

Use NuGet Package Manager to install the Ninject library. In Visual Studio, from the **Tools** menu select **NuGet Package Manager** > **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Ninject -Version 3.0.1.10
```

Replace the SignalR Dependency Resolver

To use Ninject within SignalR, create a class that derives from **DefaultDependencyResolver**.

```
internal class NinjectSignalRDependencyResolver : DefaultDependencyResolver
{
    private readonly IKernel _kernel;
    public NinjectSignalRDependencyResolver(IKernel kernel)
    {
        _kernel = kernel;
    }

    public override object GetService(Type serviceType)
    {
        return _kernel.TryGet(serviceType) ?? base.GetService(serviceType);
    }

    public override IEnumerable<object> GetServices(Type serviceType)
    {
        return _kernel.GetAll(serviceType).Concat(base.GetServices(serviceType));
    }
}
```

This class overrides the **GetService** and **GetServices** methods of **DefaultDependencyResolver**. SignalR calls these methods to create various objects at runtime, including hub instances, as well as various services used internally by SignalR.

- The **GetService** method creates a single instance of a type. Override this method to call the Ninject kernel's **TryGet** method. If that method returns null, fall back to the default resolver.
- The **GetServices** method creates a collection of objects of a specified type. Override this method to concatenate the results from Ninject with the results from the default resolver.

Configure Ninject Bindings

Now we'll use Ninject to declare type bindings.

Open the file RegisterHubs.cs. In the `RegisterHubs.Start` method, create the Ninject container, which Ninject calls the *kernel*.

```
var kernel = new StandardKernel();
```

Create an instance of our custom dependency resolver:

```
var resolver = new NinjectSignalRDependencyResolver(kernel);
```

Create a binding for `IStockTicker` as follows:

```
kernel.Bind<IStockTicker>()
    .To<Microsoft.AspNet.SignalR.StockTicker.StockTicker>()  // Bind to StockTicker.
    .InSingletonScope();  // Make it a singleton object.
```

This code is saying two things. First, whenever the application needs an `IStockTicker`, the kernel should create an instance of `StockTicker`. Second, the `StockTicker` class should be a created as a singleton object. Ninject will create one instance of the object, and return the same instance for each request.

Create a binding for **IHubConnectionContext** as follows:

```
kernel.Bind<IHubConnectionContext>().ToMethod(context =>
    resolver.Resolve<IConnectionManager>().GetHubContext<StockTickerHub>().Clients
).WhenInjectedInto<IStockTicker>();
```

This code creates an anonymous function that returns an **IHubConnection**. The **WhenInjectedInto** method tells Ninject to use this function only when creating `IStockTicker` instances. The reason is that SignalR creates **IHubConnectionContext** instances internally, and we don't want to override how SignalR creates them. This function only applies to our `StockTicker` class.

Pass the dependency resolver into the **MapHubs** method:

```
RouteTable.Routes.MapHubs(config);
```

Now SignalR will use the resolver specified in **MapHubs**, instead of the default resolver.

Here is the complete code listing for `RegisterHubs.Start`.

```
public static class RegisterHubs
{
    public static void Start()
    {
        var kernel = new StandardKernel();
        var resolver = new NinjectSignalRDependencyResolver(kernel);

        kernel.Bind<IStockTicker>()
            .To<Microsoft.AspNet.SignalR.StockTicker.StockTicker>()
            .InSingletonScope();

        kernel.Bind<IHubConnectionContext>().ToMethod(context =>
                resolver.Resolve<IConnectionManager>().
                    GetHubContext<StockTickerHub>().Clients
            ).WhenInjectedInto<IStockTicker>();

        var config = new HubConfiguration()
        {
            Resolver = resolver
        };

        // Register the default hubs route: ~/signalr/hubs
        RouteTable.Routes.MapHubs(config);
    }
}
```

To run the StockTicker application in Visual Studio, press F5. In the browser window, navigate to `http://localhost:*port*/SignalR.Sample/StockTicker.html`.

The application has exactly the same functionality as before. (For a description, see Server Broadcast with ASP.NET SignalR.) We haven't changed the behavior; just made the code easier to test, maintain, and evolve.

Develop Mobile Apps

Cloud-Connected Mobile Apps

Part 1 - Create a Web Service with Azure Web Apps and WebJobs

In the first part of a two-part article, the authors explore some of the issues involved in creating a cloud back end that aggregates and processes data and serves it to mobile clients.

Part 2 - Build a Xamarin App with Authentication and Offline Support

In the second article in their series, the authors discuss how they use Xamarin to target multiple mobile client platforms, and show how to implement authentication and maintain a synchronized client-side cache of the data.

Calling Web API from a Windows Phone 8 Application

This end-to-end tutorial shows how to create an ASP.NET Web API application that provides data to a Windows Phone 8 application.

Get Started with Azure Mobile Services

Get started using Azure Mobile Services with ASP.NET Web API. This tutorial shows how to create a Mobile Services app from the Azure Management Portal.

Authentication in Azure Mobile Services

This tutorial shows how to authenticate users in Azure Mobile Services from your app.

Using Push Notifications in Azure Mobile Services

Use Azure Mobile Services to send push notifications to a mobile device.

Develop Mobile Sites

Deploy an Mobile-Friendly ASP.NET MVC 5 Web Application on Windows Azure Web Sites

This tutorial will teach you the basics of how to deploy an MVC 5 application to a Windows Azure web site and create mobile-friendly views using responsive Bootstrap design.

Add mobile pages to your ASP.NET Web Forms / MVC application

This How To describes various ways to serve pages optimized for mobile devices from your ASP.NET Web Forms / MVC application, and suggests architectural and design issues to consider when targeting a broad range of devices.

Detect the latest mobile devices using 51degrees.mobi Foundation

51degrees.mobi Foundation is a third-party open source project that enhances ASP.NET's Request.Browser API so you can easily detect recently-released mobile devices including Windows Phone 7, Android, and Apple iPad.

Mobile Web Sites with ASP.NET MVC and the Mobile Browser Definition File

In this talk presented at the Microsoft MIX conference, Scott Hanselman discusses how you can create mobile device friendly websites using ASP.NET MVC.

Develop iPhone applications with ASP.NET

ComponentOne Studio for iPhone is a suite of ASP.NET controls that mimic the look and feel of the iPhone and iPod

touch user interfaces when rendered in Mobile Safari.

ASP.NET Mobile Controls Tested Devices

2/20/2020 • 11 minutes to read • Edit Online

The following devices and browsers have been tested with the Microsoft Mobile Internet Toolkit v1.0 and ASP.NET mobile controls.

- Microsoft Mobile Internet Toolkit [MMIT 1.0]: *(January 15, 2002)*
- Device Update 1 [DU 1.0]: *(May 14, 2002)*
- Device Update 2 [DU 2.0]: *(October 28, 2002)*
- Device Update 3 [DU 3.0]: *(August 5, 2003)*
- Device Update 4 [DU 4.0]: *(December 18, 2003)*

Single Page Application: KnockoutJS template

2/20/2020 • 12 minutes to read • Edit Online

by Mike Wasson

> The Knockout MVC Template is part of ASP.NET and Web Tools 2012.2
>
> Download ASP.NET and Web Tools 2012.2

The ASP.NET and Web Tools 2012.2 update includes a Single-Page Application (SPA) template for ASP.NET MVC 4. This template is designed to get you started quickly building interactive client-side web apps.

"Single-page application" (SPA) is the general term for a web application that loads a single HTML page and then updates the page dynamically, instead of loading new pages. After the initial page load, the SPA talks with the server through AJAX requests.

AJAX is nothing new, but today there are JavaScript frameworks that make it easier to build and maintain a large sophisticated SPA application. Also, HTML 5 and CSS3 are making it easier to create rich UIs.

To get you started, the SPA template creates a sample "To-do list" application. In this tutorial, we'll take a guided tour of the template. First we'll look at the To-do list application itself, then examine the technology pieces that make it work.

Create a New SPA Template Project

Requirements:

- Visual Studio 2012 or Visual Studio Express 2012 for Web
- ASP.NET Web Tools 2012.2 update. You can install the update here.

Start Visual Studio and select **New Project** from the Start page. Or, from the **File** menu, select **New** and then **Project**.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project and click **OK**.

In the **New Project** wizard, select **Single Page Application**.

Press F5 to build and run the application. When the application first runs, it displays a login screen.

Click the "Sign up" link and create a new user.

After you log in, the application creates a default Todo list with two items. You can click "Add Todo list" to add a new list.

Rename the list, add items to the list, and check them off. You can also delete items or delete an entire list. The changes are automatically persisted to a database on the server (actually LocalDB at this point, because you are running the application locally).

Architecture of the SPA Template

This diagram shows the main building blocks for the application.

On the server side, ASP.NET MVC serves the HTML and also handles forms-based authentication.

ASP.NET Web API handles all requests that relate to the ToDoLists and ToDoItems, including getting, creating, updating and deleting. The client exchanges data with Web API in JSON format.

Entity Framework (EF) is the O/RM layer. It mediates between the object-oriented world of ASP.NET and the underlying database. The database uses LocalDB but you can change this in the Web.config file. Typically you would use LocalDB for local development and then deploy to a SQL database on the server, using EF code-first migration.

On the client side, the Knockout.js library handles page updates from AJAX requests. Knockout uses data binding to synchronize the page with the latest data. That way, you don't have to write any of the code that walks through the JSON data and updates the DOM. Instead, you put declarative attributes in the HTML that tell Knockout how to present the data.

A big advantage of this architecture is that it separates the presentation layer from the application logic. You can create the Web API portion without knowing anything about how your web page will look. On the client side, you create a "view model" to represent that data, and the view model uses Knockout to bind to the HTML. That lets you easily change the HTML without changing the view model. (We'll look at Knockout a bit later.)

Models

In the Visual Studio project, the Models folder contains the models that are used on the server side. (There are also models on the client side; we'll get to those.)

TodoItem, TodoList

These are the database models for Entity Framework Code First. Notice that these models have properties that point to each other. `ToDoList` contains a collection of ToDoItems, and each `ToDoItem` has a reference back to its parent ToDoList. These properties are called navigation properties, and they represent the one-to-many relation a to-do list and its to-do items.

The `ToDoItem` class also uses the **[ForeignKey]** attribute to specify that `ToDoListId` is a foreign key into the `ToDoList` table. This tells EF to add a foreign-key constraint to the database.

```
[ForeignKey("TodoList")]
public int TodoListId { get; set; }
public virtual TodoList TodoList { get; set; }
```

TodoItemDto, TodoListDto

These classes define the data that will be sent to the client. "DTO" stands for "data transfer object." The DTO defines how the entities will be serialized into JSON. In general, there are several reasons to use DTOs:

- To control which properties are serialized. The DTO can contain a subset of the properties from the domain model. You might do this for security reasons (to hide sensitive data) or simply to reduce the amount of data that you send.
- To change the shape of the data – e.g. to flatten a more complex data structure.

- To keep any business logic out of the DTO (separation of concerns).
- If your domain models cannot be serialized for some reason. For example, circular references can cause problems when you serialize an object There are ways to handle this problem in Web API (see Handling Circular Object References); but using a DTO simply avoids the problem altogether.

In the SPA template, the DTOs contains the same data as the domain models. However, they are still useful because they avoid circular references from the navigation properties, and they demonstrate the general DTO pattern.

AccountModels.cs

This file contains models for site membership. The `UserProfile` class defines the schema for user profiles in the membership DB. (In this case, the only information is the user ID and the user name.) The other model classes in this file are used to create the user registration and login forms.

Entity Framework

The SPA template uses EF Code First. In Code First development, you define the models first in code, and then EF uses the model to create the database. You can also use EF with an existing database (Database First).

The `TodoItemContext` class in the Models folder derives from **DbContext**. This class provides the "glue" between the models and EF. The `TodoItemContext` holds a `ToDoItem` collection and a `TodoList` collection. To query the database, you simply write a LINQ query against these collections. For example, here is how you can select all of the to-do lists for user "Alice":

```
TodoItemContext db = new TodoItemContext();
IEnumerable<TodoList> lists =
    from td in db.TodoLists where td.UserId == "Alice" select td;
```

You can also add new items to the collection, update items, or delete items from the collection, and persist the changes to the database.

ASP.NET Web API Controllers

In ASP.NET Web API, controllers are objects that handle HTTP requests. As mentioned, the SPA template uses Web API to enable CRUD operations on `ToDoList` and `ToDoItem` instances. The controllers are located in the Controllers folder of the solution.

- `TodoController`: Handles HTTP requests for to-do items
- `TodoListController`: Handles HTTP requests for to-do lists.

These names are significant, because Web API matches the URI path to the controller name. (To learn how Web API routes HTTP requests to controllers, see Routing in ASP.NET Web API.)

Let's look at the `ToDoListController` class. It contains a single data member:

```
private TodoItemContext db = new TodoItemContext();
```

The `TodoItemContext` is used to communicate with EF, as described earlier. The methods on the controller

implement the CRUD operations. Web API maps HTTP requests from the client to controller methods, as follows:

HTTP REQUEST	CONTROLLER METHOD	DESCRIPTION
GET /api/todo	`GetTodoLists`	Gets a collection of to-do lists.
GET /api/todo/*id*	`GetTodoList`	Gets a to-do list by ID
PUT /api/todo/*id*	`PutTodoList`	Updates a to-do list.
POST /api/todo	`PostTodoList`	Creates a new to-do list.
DELETE /api/todo/*id*	`DeleteTodoList`	Deletes a TODO list.

Notice that the URIs for some operations contain placeholders for the ID value. For example, to delete a to-list with an ID of 42, the URI is `/api/todo/42`.

To learn more about using Web API for CRUD operations, see Creating a Web API that Supports CRUD Operations. The code for this controller is fairly straightforward. Here are some interesting points:

- The `GetTodoLists` method uses a LINQ query to filter the results by the ID of the logged-in user. That way, a user only sees the data that belongs to him or her. Also, notice that a Select statement is used to convert the `ToDoList` instances into `TodoListDto` instances.
- The PUT and POST methods check the model state before modifying the database. If **ModelState.IsValid** is false, these methods return HTTP 400, Bad Request. Read more about model validation in Web API at Model Validation.
- The controller class is also decorated with the **[Authorize]** attribute. This attribute checks whether the HTTP request is authenticated. If the request is not authenticated, the client receives HTTP 401, Unauthorized. Read more about authentication at Authentication and Authorization in ASP.NET Web API.

The `TodoController` class is very similar to `TodoListController`. The biggest difference is that it does not define any GET methods, because the client will get the to-do items along with each to-do list.

MVC Controllers and Views

The MVC controllers are also located in the Controllers folder of the solution. `HomeController` renders the main HTML for the application. The view for the Home controller is defined in Views/Home/Index.cshtml. The Home view renders different content depending on whether the user is logged in:

```
@if (@User.Identity.IsAuthenticated)
{
    // ....
}
```

When users are logged in, they see the main UI. Otherwise, they see the login panel. Note that this conditional rendering happens on the server side. Never try to hide sensitive content on the client side—anything that you send in an HTTP response is visible to someone who is watching the raw HTTP messages.

Client-Side JavaScript and Knockout.js

Now let's turn from the server side of the application to the client. The SPA template uses a combination of jQuery and Knockout.js to create a smooth, interactive UI. Knockout.js is a JavaScript library that makes it easy to bind HTML to data. Knockout.js uses a pattern called "Model-View-ViewModel."

- The model is the domain data (ToDo lists and ToDo items).
- The view is the HTML document.
- The view-model is a JavaScript object that holds the model data. The view-model is a code abstraction of the UI. It has no knowledge of the HTML representation. Instead, it represents abstract features of the view, such as "a list of ToDo items".

The view is data-bound to the view-model. Updates to the view-model are automatically reflected in the view. Bindings work the other direction as well. Events in the DOM (such as clicks) are data-bound to functions on the view model, which trigger AJAX calls.

The SPA template organizes the client-side JavaScript into three layers:

- todo.datacontext.js: Sends AJAX requests.
- todo.model.js: Defines the models.
- todo.viewmodel.js: Defines the view model.

These script files are located in the Scripts/app folder of the solution.

todo.datacontext handles all AJAX calls to the Web API controllers. (The AJAX calls for logging in are defined elsewhere, in ajaxlogin.js.)

todo.model.js defines the client-side (browser) models for the to-do lists. There are two model classes: todoItem and todoList.

Many of the properties in the model classes are of type "ko.observable". Observables are how Knockout does its magic. From the Knockout documentation: An observable is a "JavaScript object that can notify subscribers about changes." When the value of an observable changes, Knockout updates any HTML elements that are bound to those observables. For example, todoItem has observables for the title and isDone properties:

```
self.title = ko.observable(data.title);
self.isDone = ko.observable(data.isDone);
```

You can also subscribe to an observable in code. For example, the todoItem class subscribes to changes in the "isDone" and "title" properties:

```
saveChanges = function () {
    return datacontext.saveChangedTodoItem(self);
};

// Auto-save when these properties change
self.isDone.subscribe(saveChanges);
self.title.subscribe(saveChanges);
```

View Model

The view model is defined in todo.viewmodel.js. The view model is the central point where the application binds the HTML page elements to the domain data. In the SPA template, the view model contains an observable array of todoLists. The following code in the view model tells Knockout to apply the bindings:

```
ko.applyBindings(window.todoApp.todoListViewModel);
```

HTML and Data Binding

The main HTML for the page is defined in Views/Home/Index.cshtml. Because we are using data-binding, the HTML is only a template for what actually gets rendered. Knockout uses *declarative* bindings. You bind page elements to data by adding a "data-bind" attribute to the element. Here is a very simple example, taken from the Knockout documentation:

```
<p>There are <span data-bind="text: myItems().count"></span> items<p>
```

In this example, Knockout updates the contents of the **** element with the value of `myItems.count()`. Whenever this value changes, Knockout updates the document.

Knockout provides a number of different binding types. Here are some of the bindings used in the SPA template:

- **foreach**: Lets you iterate through a loop and apply the same markup to each item in the list. This is used to render the to-do lists and to-do items. Within the **foreach**, the bindings are applied to the elements of the list.
- **visible**: Used to toggle visibility. Hide markup when a collection is empty, or make the error message visible.
- **value**: Used to populate form values.
- **click**: Binds a click event to a function on the view model.

Anti-CSRF Protection

Cross-Site Request Forgery (CSRF) is an attack where a malicious site sends a request to a vulnerable site where the user is currently logged in. To help prevent CSRF attacks, ASP.NET MVC uses *anti-forgery tokens*, also called request verification tokens. The idea is that the server puts a randomly generated token into a web page. When the client submits data to the server, it must include this value in the request message.

Anti-forgery tokens work because the malicious page cannot read the user's tokens, due to same-origin policies. (Same-origin policies prevent documents hosted on two different sites from accessing each other's content.)

ASP.NET MVC provides built-in support for anti-forgery tokens, through the AntiForgery class and the [ValidateAntiForgeryToken] attribute. Currently, this functionality is not built into Web API. However, the SPA template includes a custom implementation for Web API. This code is defined in the `ValidateHttpAntiForgeryTokenAttribute` class, which is located in the Filters folder of the solution. To learn more about anti-CSRF in Web API, see Preventing Cross-Site Request Forgery (CSRF) Attacks.

Conclusion

The SPA template is designed to get you started quickly writing modern, interactive web applications. It uses the Knockout.js library to separate presentation (HTML markup) from the data and application logic. But Knockout is not the only JavaScript library you can use to create a SPA. If you want to explore some other options, take a look at the community-created SPA templates.

Know a library other than Knockout?

2/20/2020 • 2 minutes to read • Edit Online

by Mads Kristensen

The Single Page Application (SPA) template is a great way to get started writing single-page applications. The template uses KnockoutJS to bind application data to DOM elements.

But Knockout is not the only JavaScript library for creating rich client applications. Other libraries solve similar challenges in different ways. You might prefer a one library over another, so we've made several community-created templates available for download. Each of these templates uses a different mix of client JavaScript libraries.

To install a community-created template, visit one of the template pages listed below and click the Download button. The templates are provided as VSIX files.

BackboneJS

Backbone.js SPA template. This template provides an initial skeleton for developing a Backbone.js application in ASP.NET MVC. Out of the box it provides basic user login functionality, including user sign-up, sign-in, password reset, and user confirmation with basic email templates.

BreezeJS

BreezeJS is an open source library for managing rich data in a JavaScript client. Breeze handles querying, caching, change tracking, validation, and more. Two templates feature Breeze:

- The Breeze/Knockout template extends the Knockout SPA template, showing how easily you can build a single-page application with Breeze for data management and KnockoutJS for data binding.
- The Breeze/Angular template also extends the Knockout SPA template with Breeze, but using the AngularJS library for data binding, dependency injection, and screen management.

In addition, the Hot Towel SPA template uses BreezeJS.

EmberJS

EmberJS SPA template. This template uses Ember, a powerful MVC JavaScript library that solves a wide array of challenges for building rich client applications.

The Ember SPA template is a re-implementation of the Knockout SPA template, using EmberJS and Handlebars templating.

Hot Towel

Hot Towel SPA template. This template brings in several JavaScript libraries, including Breeze, Knockout, RequireJS and Twitter Bootstrap.

Compared with the other templates listed here, the Hot Towel template provides a more complete application from which you can build your own. There are more concepts to be aware of, but once you understand them, this template might just be what you are looking for. If you want to build a SPA but can't decide where to start, use Hot Towel and in seconds you'll have a SPA and all the tools you need to build on it.

Feature table

Here are the features provided by each SPA template:

	ASP.NET SPA	BACKBONE	BREEZE/ANGULAR	BREEZE/KO	EMBER	HOT TOWEL
ToDo sample	✓		✓	✓	✓	
Bare template		✓				✓
Navigation and history		✓	✓		✓	✓
Libraries						
Angular			✓			
Backbone		✓				
Breeze			✓	✓		✓
Durandal						✓
Ember					✓	
Knockout	✓			✓		✓

> Download the Backbone.js SPA Template

The Backbone.js SPA template is designed to get you started quickly building interactive client-side web apps using Backbone.js.

The template provides an initial skeleton for developing a Backbone.js application in ASP.NET MVC. Out of the box it provides basic user login functionality, including user sign-up, sign-in, password reset, and user confirmation with basic email templates.

Requirements:

- ASP.NET and Web Tools 2012.2 update

Create a Backbone Template Project

Download and install the template by clicking the Download button above. The template is packaged as a Visual Studio Extension (VSIX) file. You might need to restart Visual Studio.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project and click **OK**.

In the **New Project** wizard, select Backbone.js SPA Project.

Press Ctrl-F5 to build and run the application without debugging, or press F5 to run with debugging.

Clicking "My Account" brings up the login page:

Walkthrough: Client Code

Let's starts with the client side. The client application scripts are located in the ~/Scripts/application folder. The application is written in TypeScript (.ts files) which are compiled into JavaScript (.js files).

Application

`Application` is defined in application.ts. This object initializes the application and acts as the root namespace. It maintains configuration and state information that is shared across the application, such as whether the user is signed in.

The `application.start` method creates the modal views and attaches event handlers for application-level events, such as user sign-in. Next, it creates the default router and checks whether any client-side URL is specified. If not, it redirects to the default url (#!/).

Events

Events are always important when developing loosely coupled components. Applications often perform multiple operations in response to a user action. Backbone provides built-in events with components such as Model, Collection, and View. Instead of creating inter-dependencies among these components, the template uses a "pub/sub" model: The `events` object, defined in events.ts, acts as an event hub for publishing and subscribing to application events. The `events` object is a singleton. The following code shows how to subscribe to an event and then trigger the event:

```
events.on('myEvent', (e: MyEventArg) => {
    // Do your work
});

// Later in the code
events.trigger('myEvent', { arg: 'myValue' });
```

Router

In Backbone.js, a router provides methods for routing client-side pages and connecting them to actions and events. The template defines a single router, in router.ts. The router creates the activable views and maintains the state

when switching views. (Activable views are described in the next section.) Initially, the project has two dummy views, Home and About. It also has a NotFound view, which is displayed if the route is not known.

Views

The views are defined in ~/Scripts/application/views. There are two kinds of views, activable views and modal dialog views. Activable views are invoked by the router. When an activable view is shown, all other activable views become inactive. To create an activable view, extend the view with the `Activable` object:

```
export class MyView extends Backbone.View {
    // Other implementation details
}

// Extending with Activable
_.extend(MyView.prototype, Activable);
```

Extending with `Activable` adds two new methods to the view, `activate` and `deactivate`. The router calls these methods to activate and deactive the view.

Modal views are implemented as Twitter Bootstrap modal dialogs. The `Membership` and `Profile` views are modal views. Model views can be invoked by any application events. For example, in the `Navigation` view, clicking the "My Account" link shows either the `Membership` view or the `Profile` view, depending on whether the user is logged in. The `Navigation` attaches click event handlers to any child elements that have the `data-command` attribute. Here is the HTML markup:

```
<li>
  <a href="#" data-command="myAccount">
    <i class="icon-user"></i> My Account
  </a>
</li>
```

Here is the code in navigation.ts to hook up the events:

```
export class Navigation extends Backbone.View {
    // Other implementation details
    handleCommand(e: JQueryEventObject) {
        var command = $(e.currentTarget).attr('data-command');
        if (command) {
            events.trigger(command);
        }
    }
}
Navigation.prototype.events = () => {
    return {
        'click [data-command]': 'handleCommand'
    };
};
```

Models

The models are defined in ~/Scripts/application/models. The models all have three basic things: default attributes, validation rules, and a server-side end point. Here is a typical example:

```
export class Session extends Backbone.Model {
    urlRoot() {
        return serverUrlPrefix + '/sessions'
    }

    defaults(): ISessionAttributes {
        return {
          email: null,
          password: null,
          rememberMe: false
        }
    }

    validate(attributes: ISessionAttributes): IValidationResult {
        var errors = {};

        if (!attributes.email) {
            Validation.addError(errors, 'email', 'Email is required.');
        }

        if (!attributes.password) {
            Validation.addError(errors, 'password', 'Password is required.');
        }

        if (!_.isEmpty(errors)) {
            return { errors: errors };
        }
    }
}
```

Plug-ins

The ~/Scripts/application/lib folder contains a few handy jQuery plug-ins. The form.ts file defines a plug-in for working with form data. Often you need to serialize or deserialize form data and show any model validation errors. The form.ts plug-in has methods such as `serializeFields`, `deserializeFields`, and `showFieldErrors`. The following example shows how to serialize a form to a model.

```
// Here $el is the form element
// Hide existing errors if there is any
this.$el.hideSummaryError().hideFieldErrors();

// Subscribe invalid event which
// is fired when validation fails
model.on('invalid', () =>
    this.$el.showFieldErrors{(
        errors: model.validationError.errors;
    )}
);

model.save(this.$el.serializeFields(), {
    success: () => { }, // lets do something good
    error: (m, jqxhr: JQueryXHR) => {
        if (jqxhr.status === 400) { // bad request
            // Handle server side field errors
            var response = <any>$.parseJSON(jqxhr.responseText);
            if (response && _.has(response, 'ModelState')) {
                return this.$el.showFieldErrors({
                    errors: response.ModelState
                });
            }
        }

        // All other server errors
        this.$el.showSummaryError({
            message: 'An unexpected error has occurred while performing ' +
                'operation.'
        });
    }
});
```

The flashbar.ts plug-in gives various kinds of feedback messages to the user. The methods are `$.showSuccessbar`, `$.showErrorbar` and `$.showInfobar`. Behind the scenes, it uses Twitter Bootstrap alerts to show nicely animated messages.

The confirm.ts plug-in replaces the browser's confirm dialog, although the API is somewhat different:

```
$.confirm({
    prompt: 'Are you sure you want to do it?',
    ok: => { //Do something useful },
    cancel: => { // Do something else }
)};
```

Walkthrough: Server Code

Now let's look at the server side.

Controllers

In a single page application, the server plays only a small role in the user interface. Typically, the server renders the initial page and then sends and receives JSON data.

The template has two MVC controllers: `HomeController` renders the initial page, and `SupportsController` is used to confirm new user accounts and reset passwords. All other controllers in the template are ASP.NET Web API controllers, which send and receive JSON data. By default, the controllers use the new `WebSecurity` class to perform user-related tasks. However, they also have optional constructors that let you pass in delegates for these tasks. This makes testing easier, and lets you replace `WebSecurity` with something else, by using an IoC Container. Here is an example:

```
public class SessionsController : ApiController
{
    private readonly Func<string, string, bool, bool> signIn;
    private readonly Action signOut;

    public SessionsController() : this(WebSecurity.Login, WebSecurity.Logout)
    {
    }

    public SessionsController(
        Func<string, string, bool, bool> signIn,
        Action signOut)
    {
      this.signIn = signIn;
      this.signOut = signOut;
    }

    // Rest of the code
}
```

Views

The views are designed to be modular: Each section of a page has its own dedicated view. In a single page application, it is common to include views that do not have any corresponding controller. You can include a view by calling `@Html.Partial('myView')`, but this gets tedious. To make this easier, the template defines a helper method, `IncludeClientViews`, that renders all of the views in a specified folder:

```
@Html.IncludeClientViews('yourViewFolder')
```

If the folder name is not specified, the default folder name is "ClientViews". If your client view also uses partial views, name the partial view with an underscore character (for example, `_SignUp`). The `IncludeClientViews` method excludes any views whose name starts with an underscore. To include a partial view in the client view, call `Html.ClientView('SignUp')` instead of `Html.Partial('_SignUp')`.

Sending Email

To send email, the template uses Postal. However, Postal is abstracted from the rest of the code with the `IMailer` interface, so you can easily replace it with another implementation. The email templates are located in the Views/Emails folder. The sender's email address is specified in the web.config file, in the `sender.email` key of the **appSettings** section. Also, when `debug="true"` in web.config, the application does not require user email confirmation, to speed up development.

GitHub

You can also find the Backbone.js SPA template on GitHub.

Breeze/Angular template

2/20/2020 • 5 minutes to read • Edit Online

by Mads Kristensen

> The Breeze/Angular MVC Template was written by Ward Bell
>
> Download the Breeze/Angular MVC Template

AngularJS is an open source library from Google for building Single Page Applications (SPAs). It offers data binding, dependency injection, and screen management. Combine it with BreezeJS, another open source library for data modeling and data management, and you have the essential ingredients for a great HTML/JavaScript client app.

The Breeze/Angular SPA template is a variation on the KnockoutJS SPA template included in the ASP.NET and Web Tools 2012.2 Update. If you've got Visual Studio, you'll have an example SPA up and running in less than 60 seconds.

Outwardly, the application looks the very similar to the KnockoutJS SPA template. But it's quite different under the hood. The KnockoutJS template uses Knockout for data binding and raw AJAX for data access. The Breeze/Angular template uses Angular for data binding and Breeze for data access. These libraries enable additional capabilities, including page navigation and history.

Here is the application's About page:

This page displays a running log of events during the current user session, including:

- Paging. Note the Todo controller creation at #2 and #7.
- Remote queries (#3) and local cache queries (#7).
- Saving new (#5, #6) and modified (#4) entities.
- Changes validated on the client (#9), so the user can correct mistakes before committing changes to the database.

There's more to explore in this template, including:

- Dynamic loading of HTML view templates.
- Custom data binding through Angular "directives."
- Modularity and dependency injection.
- Query filters, sorts, paging, projections, and inclusion of related entities.
- Sharing data across multiple screens.
- Saving multiple changes as a single transaction.
- Validation rules propagated automatically from the server to the JavaScript client.

Let's get started.

Create a Breeze/Angular Template Project

Download and install the template by clicking the Download button above. The template is packaged as a Visual Studio Extension (VSIX) file. You might need to restart Visual Studio.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project and click **OK**.

In the **New Project** wizard, select **Breeze Angular SPA**.

Press Ctrl-F5 to build and run the application without debugging, or press F5 to run with debugging.

When the application first runs, it displays a login screen. Click the "Sign up" link and a new page glides into view, where you can enter a username and password. (The login and registration pages are built using ASP.NET MVC.) When you submit the registration form, the server generates a TodoList with two items for your account. Then it presents them to you on a yellow note.

Now you are in the land of SPA. Everything you see and experience while manipulating Todos is rendered and managed on the client with the help of Knockout and Breeze. Explore the app as a user ... but with a developer's eye. Use the developer tools in your browser to capture the network traffic. (In Internet Explorer: Press F12, select the **Network** tab, and click **Start capturing**.) Now try the following:

- Add a new Todo item.
- Click the label and edit the Todo item title
- Check a checkbox to mark the item done. Notice that the textbox is disabled, so the title is no longer editable.

- Click the 'x' to the right of the label. The item disappears and is deleted from the database.
- Pick another item and clear its title. You'll get a validation error that the title is required. After a brief pause, the previous title is restored.
- Type in a ridiculously long title. You'll get a different validation error that the title is too long.
- Click the "Add Todo List" button. A new list appears to the left of the previous list.
- Play with the TodoList title, triggering its required and length validations.
- Click in the title textbox to clear the error message.
- Click the "x" in the circle in the upper right corner to delete the TodoList and its todos.
- Click the "About" link in the upper right to see a log of these activities.

The validation logic is performed client-side by Breeze. Validation attributes on the server model classes are propagated to the client and executed automatically before the client contacts the server.

Review the network traffic. Notice that there were no calls to the server when Breeze detected an error. Each valid change resulted in a POST request to "/api/Todo/SaveChanges". Breeze bundles the changes and sends them together as a single request to the Web API controller's `SaveChanges` method. That's different from KnockoutJS SPA template, which makes PUT, POST, and DELETE requests for each item individually.

Also, notice there is no network traffic when you switch between the TodoList and About pages. That's because the query has been constrained to the local Breeze cache.

Peek inside

This application has a client side and a server side. The client-side stack consists of a little HTML and a combination of application JavaScript modules (in the "app" folder) plus third-party JavaScript libraries (in the "Scripts" folder).

The UI architecture separates the HTML widgets of the views from the supporting presentation code in the controllers. The Angular data-binding system coordinates views and controllers so that each can do its job without intimate knowledge of the other.

The controller asks the data context to acquire and save the model entities. The data context delegates most of the work to Breeze, which constructs self-tracking model objects from JSON query results.

The server-side stack consists of some developer code and three principle .NET libraries: Web API, Entity Framework, and Breeze.NET:

The basic architecture is the same as the KnockoutJS SPA template. However, the implementation is much simpler: The DTOs were deleted, and most of the Entity Framework details have been delegated to Breeze.NET.

Next Steps

We suggest that you explore the code, guided by the extensive discussion of both the client and the server stacks on the Breeze website.

You might try playing with Breeze client-side query; add some filters and sorts. You might add more model properties and more entities to get a better feel for end-to-end SPA development. When you are confident of the design, you can tear out the Todo features and replace them with your own.

Happy coding!

Breeze/Knockout template

2/20/2020 • 6 minutes to read • Edit Online

by Mads Kristensen

> The Breeze/Knockout MVC Template was written by Ward Bell
>
> Download the Breeze/Knockout MVC Template

You've heard of "single page application" (SPA) and wondered what it is. While you could read about it, you'd rather experience it for yourself. But who has time to download a sample? If you've got Visual Studio, you'll have an example SPA up and running in less than 60 seconds with the ASP.NET MVC 4 "Breeze/Knockout Single Page Application" template.

What is the Breeze/Knockout SPA Template?

Most project templates generate an application skeleton. You put flesh on those bones by adding your code and eventually deliver a working application. The Breeze/Knockout SPA template is different. It generates a sample application for you to study. It demonstrates a SPA application design and many of the techniques for building a SPA.

The Breeze/Knockout template is a variation on the KnockoutJS SPA template included in the ASP.NET and Web Tools 2012.2 Update. The Breeze SPA template generates an application with the same user experience, but it has a different implementation, using Breeze for data management.

The KnockoutJS SPA template makes service requests with raw jQuery AJAX, which is adequate for a simple application. But more sophisticated apps have more demanding data management requirements. For example, most applications:

- Query and re-query the server during an extended user session.
- Add query filters, sorting, and paging.

- Share the same data across multiple screens.
- Accumulate changes to many objects, then save them as a single transaction.
- Validate changes on the client, so the user can correct mistakes before committing changes to the database.

The BreezeJS library handles these chores for you, freeing you to develop the application logic and user experience that matter most.

Breeze is an open source library for building rich data applications in JavaScript and HTML, the kinds of apps that have historically been delivered as stand-alone desktop applications.

The Breeze/Knockout template helps you take that first crucial step toward a more robust data management infrastructure. It produces a sample Todo application that is outwardly identical to the KnockoutJS SPA template. On the inside, it replaces the AJAX data layer with Breeze, so you can compare the two approaches side-by-side. Of course, it barely touches the potential of a Breeze application. But you'll see how Breeze works and how little is required to make that transition.

Let's get started.

Create a Breeze/Knockout Template Project

Download and install the template by clicking the Download button above. The template is packaged as a Visual Studio Extension (VSIX) file. You might need to restart Visual Studio.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project and click **OK**.

In the **New Project** wizard, select **Breeze Knockout SPA**.

Press Ctrl-F5 to build and run the application without debugging, or press F5 to run with debugging.

When the application first runs, it displays a login screen. Click the "Sign up" link and a new page glides into view, where you can enter a username and password. (The login and registration pages are built using ASP.NET MVC.) When you submit the registration form, the server generates a TodoList with two items for your account. Then it presents them to you on a yellow note.

Now you are in the land of SPA. Everything you see and experience while manipulating Todos is rendered and managed on the client with the help of Knockout and Breeze. Explore the app as a user ... but with a developer's eye. Use the developer tools in your browser to capture the network traffic. (In Internet Explorer: Press F12, select the **Network** tab, and click **Start capturing**.) Now try the following:

- Add a new Todo item.
- Click the label and edit the Todo item title
- Check a checkbox to mark the item done. Notice that the textbox is disabled, so the title is no longer editable.
- Click the 'x' to the right of the label. The item disappears and is deleted from the database.
- Pick another item and clear its title. You'll get a validation error that the title is required. After a brief pause, the previous title is restored.
- Type in a ridiculously long title. You'll get a different validation error that the title is too long.
- Click the "Add Todo List" button. A new list appears to the left of the previous list.
- Play with the TodoList title, triggering its required and length validations.
- Click in the title textbox to clear the error message.
- Click the "x" in the circle in the upper right corner to delete the TodoList and its todos.

The validation logic is performed client-side by Breeze. Validation attributes on the server model classes are propagated to the client and executed automatically before the client contacts the server.

Review the network traffic. Notice that there were no calls to the server when Breeze detected an error. Each valid change resulted in a POST request to "/api/Todo/SaveChanges". Breeze bundles the changes and sends them together as a single request to the Web API controller's `SaveChanges` method. That's different from KnockoutJS SPA template, which makes PUT, POST, and DELETE requests for each item individually.

Peek inside

This application has a client side and a server side. The client-side stack consists of a little HTML and a combination of application JavaScript modules (in the "app" folder) plus third-party JavaScript libraries (in the "Scripts" folder).

If you've investigated the KnockoutJS SPA template, this should look very familiar. Focus on the blue boxes. The UI architecture is Model-View-ViewModel (MVVM), in which the HTML widgets of the view are cleanly separated from the supporting presentation code in the view-model. A data binding system (Knockout in this case) coordinates the view and view-model so that each can do its job without intimate knowledge of the other.

The model encapsulates the Todo data. Entities in the model are constructed by Breeze with Knockout observable properties, so they can be bound directly to widgets in the view. The view-model asks the data context to acquire and save the model entities. The data context delegates most of the work to Breeze.

The server-side stack consists of some developer code and three principle .NET libraries: Web API, Entity Framework, and Breeze.NET:

The basic architecture is the same as the KnockoutJS SPA template. However, the implementation is much simpler: The DTOs were deleted, and most of the Entity Framework details have been delegated to Breeze.NET.

Next Steps

We suggest that you explore the code, guided by the extensive discussion of both the client and the server stacks on the Breeze website.

You might try playing with Breeze client-side query; add some filters and sorts. You might add more model properties and more entities to get a better feel for end-to-end SPA development. When you are confident of the design, you can tear out the Todo features and replace them with your own.

Soon you'll be ready for the next big step: Adding client-side screens and navigating among them. You'll leave this SPA template behind and turn to a more complete SPA stack, such as John Papa's Hot Towel, which adds Durandal to the Breeze and Knockout mix.

EmberJS template

2/20/2020 • 6 minutes to read • Edit Online

by Xinyang Qiu

> The EmberJS MVC Template is written by Nathan Totten, Thiago Santos, and Xinyang Qiu.
>
> Download the EmberJS MVC Template

The EmberJS SPA template is designed to get you started quickly building interactive client-side web apps using EmberJS.

"Single-page application" (SPA) is the general term for a web application that loads a single HTML page and then updates the page dynamically, instead of loading new pages. After the initial page load, the SPA talks with the server through AJAX requests.

AJAX is nothing new, but today there are JavaScript frameworks that make it easier to build and maintain a large sophisticated SPA application. Also, HTML 5 and CSS3 are making it easier to create rich UIs.

The EmberJS SPA Template uses the Ember JavaScript library to handle page updates from AJAX requests. Ember.js uses data binding to synchronize the page with the latest data. That way, you don't have to write any of the code that walks through the JSON data and updates the DOM. Instead, you put declarative attributes in the HTML that tell Ember.js how to present the data.

On the server side, the EmberJS template is almost identical to the KnockoutJS SPA template. It uses ASP.NET MVC to serve HTML documents, and ASP.NET Web API to handle AJAX requests from the client. For more information about those aspects of the template, refer to the KnockoutJS template documentation. This topic focuses on the differences between the Knockout template and the EmberJS template.

Create an EmberJS SPA Template Project

Download and install the template by clicking the Download button above. You might need to restart Visual Studio.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project and click **OK**.

In the **New Project** wizard, select **Ember.js SPA Project**.

EmberJS SPA Template Overview

The EmberJS template uses a combination of jQuery, Ember.js, Handlebars.js to create a smooth, interactive UI.

Ember.js is a JavaScript library that uses a client-side MVC pattern.

- A *template*, written in the Handlebars templating language, describes the application user interface. In release mode, the Handlebars compiler is used to bundle and compile the handlebars template.
- A *model* stores the application data that it gets from the server (ToDo lists and ToDo items).
- A *controller* stores application state. Controllers often present model data to the corresponding templates.
- A *view* translates primitive events from the application and passes these to the controller.
- A *router* manages application state, keeping URLs and templates in sync.

In addition, the Ember Data library can be used to synchronize JSON objects (obtained from the server through a RESTful API) and the client models.

The EmberJS SPA template organizes the scripts into eight layers:

- webapi_adapter.js, webapi_serializer.js: Extends the Ember Data library to work with ASP.NET Web API.
- Scripts/helpers.js: Defines new Ember Handlebars helpers.
- Scripts/app.js: Creates the app and configures the adapter and serializer.
- Scripts/app/models/*.js: Defines the models.
- Scripts/app/views/*.js: Defines the views.
- Scripts/app/controllers/*.js: Defines the controllers.
- Scripts/app/routes, Scripts/app/router.js: Defines the routes.
- Templates/*.hbs: Defines the handlebars templates.

Let's look at some of these scripts in more detail.

Models

The models are defined in the Scripts/app/models folder. There are two model files: todoItem.js and todoList.js.

todo.model.js defines the client-side (browser) models for the to-do lists. There are two model classes: todoItem and todoList. In Ember, models are subclasses of DS.Model. A model can have properties with attributes:

```
todoItemId: attr('number'),
title: attr('string')
```

Models can define relationships to other models:

```
todoList: DS.belongsTo('App.TodoList'),
```

Models can have computed properties that bind to other properties:

```
hasError: function () {
    var currentError = this.get("error");
    return !(currentError === '' || currentError === null);
}.property('error'),
```

Models can have observer functions, which are invoked when an observed property changes:

```
saveCheckbox: function () {
    if(this.get("isDirty")){
        if (this.get("todoItemId")) {
            App.store.commit();
        }
    }
}.observes('isDone'),
```

Views

The views are defined in the Scripts/app/views folder. A view translates events from the application UI. An event handler can call back to controller functions, or simply call the data context directly.

For example, the following code is from views/TodoItemEditView.js. It defines the event handling for an input text field.

```
App.TodoItemEditView = Em.TextField.extend({
    lastValue: '',
    focusIn: function (evt) {
        this.lastValue = this.get('parentView').templateData.view.content.get("title");
    },
    focusOut: function (evt) {
        this.changeContent();
    },

    insertNewline: function (evt) {
        $(evt.target).blur();
    },

    changeContent: function () {
        var todoItem = this.get('parentView').templateData.view.content;
        var newValue = todoItem.get("title");
        if (this.lastValue != newValue) {
            App.store.commit();
            this.lastValue = newValue;
        }
    }
});
```

Controller

The controllers are defined in the Scripts/app/controllers folder. To represent a single model, extend `Ember.ObjectController`:

```
App.TodoItemController = Ember.ObjectController.extend({
});
```

A controller can also represent a collection of models by extending `Ember.ArrayController`. For example, the TodoListController represents an array of `todoList` objects. The controller sorts by todoList ID, in descending order:

```
App.TodoListController = Ember.ArrayController.extend({
    error: "",
    sortProperties: ['todoListId'],
    sortAscending: true,

    // ...
```

The controller defines a function named `addTodoList`, which creates a new todoList and adds it to the array. To see how this function gets called, open the template file named todoListTemplate.html, in the Templates folder. The following template code binds a button to the `addTodoList` function:

```
<input type="button" {{action "addTodoList"}} class="isActive" value="Add Todo list"></input>
```

The controller also contains an `error` property, which holds an error message. Here is the template code to

display the error message (also in todoListTemplate.html):

```
<p class="error">{{error}}</p>
```

Routes

Router.js defines the routes and the default template to display, sets up application state, and matches URLs to routes:

```
App.Router.map(function () {
    this.route("index", { path: "/" });
    this.route("about");
    this.route("todoList", { path: "/todo" });
});
```

TodoListRoute.js loads data for the TodoListRoute by overriding the setupController function:

```
App.TodoListRoute = Ember.Route.extend({
    setupController: function (controller, model) {
        controller.set('content', App.TodoList.find());
    }
});
```

Ember uses naming conventions to match URLs, route names, controllers, and templates. For more information, see http://emberjs.com/guides/routing/defining-your-routes/ at the EmberJS documentation.

Templates

The Templates folder contains four templates:

- application.hbs: The default template that is rendered when the application is started.
- about.hbs: The template for the "/about" route.
- index.hbs: The template for the root "/" route.
- todoList.hbs: The template for the "/todo" route.
- _navbar.hbs: The template defines the navigation menu.

The application template acts like a master page. It contains a header, a footer, and an "{{outlet}}" to insert other templates in depending on the route. For more information about application templates in Ember, see http://guides.emberjs.com/v1.10.0/templates/the-application-template//.

The "/todoList" template contains two loop expressions. The outside loop is `{{#each controller}}`, and the inside loop is `{{#each todos}}`. The following code shows a built-in `Ember.Checkbox` view, a customized `App.TodoItemEditView`, and a link with a `deleteTodo` action.

```
{{view Ember.Checkbox checkedBinding="isDone"}}

{{view App.TodoItemEditView valueBinding="title" class="required" disabledBinding="isDone"}}

<a href="#" {{action "deleteTodo" on="click" target="view"}}>X</a>
```

The `HtmlHelperExtensions` class, defined in Controllers/HtmlHelperExtensions.cs, defines a helper function to cache and insert template files when **debug** is set to **true** in the Web.config file. This function is called from the ASP.NET MVC view file defined in Views/Home/App.cshtml:

```
@if (HttpContext.Current.IsDebuggingEnabled)
{
    @Html.RenderEmber()
}
else
{
    @Scripts.Render("~/bundles/templates")
}
```

Called with no arguments, the function renders all of the template files in the Templates folder. You can also specify a subfolder or a specific template file.

When **debug** is **false** in Web.config, the application includes the bundle item "~/bundles/templates". This bundle item is added in BundleConfig.cs, using the Handlebars compiler library:

```
if (!HttpContext.Current.IsDebuggingEnabled)
{
    bundles.Add(new Bundle("~/bundles/templates",
        new EmberHandlebarsBundleTransform()).Include(
            "~/scripts/app/templates/*.hbs"
        ));
}
```

Hot Towel template

2/20/2020 • 6 minutes to read • Edit Online

by Mads Kristensen

> The Hot Towel MVC Template is written by John Papa

> Hot Towel MVC Template for Visual Studio 2013
>
> Hot Towel: Because you don't want to go to the SPA without one!

Want to build a SPA but can't decide where to start? Use Hot Towel and in seconds you'll have a SPA and all the tools you need to build on it!

Hot Towel creates a great starting point for building a Single Page Application (SPA) with ASP.NET. Out of the box you it provides a modular structure for your code, view navigation, data binding, rich data management and simple but elegant styling. Hot Towel provides everything you need to build a SPA, so you can focus on your app, not the plumbing.

> Learn more about building a SPA from John Papa's videos, tutorials and Pluralsight courses.

Application Structure

Hot Towel SPA provides an App folder which contains the JavaScript and HTML files that define your application.

Inside the App folder:

- durandal
- services
- viewmodels
- views

The App folder contains a collection of modules. These modules encapsulate functionality and declare dependencies on other modules. The views folder contains the HTML for your application and the viewmodels folder contains the presentation logic for the views (a common MVVM pattern). The services folder is ideal for housing any common services that your application may need such as HTTP data retrieval or local storage interaction. It is common for multiple viewmodels to re-use code from the service modules.

ASP.NET MVC Server Side Application Structure

Hot Towel builds on the familiar and powerful ASP.NET MVC structure.

- App_Start
- Content
- Controllers
- Models
- Scripts
- Views

Featured Libraries

- ASP.NET MVC
- ASP.NET Web API
- ASP.NET Web Optimization - bundling and minification
- Breeze.js - rich data management
- Durandal.js - navigation and View composition
- Knockout.js - data bindings
- Require.js - Modularity with AMD and optimization
- Toastr.js - pop-up messages
- Twitter Bootstrap - robust CSS styling

Installing via the Visual Studio 2012 Hot Towel SPA Template

Hot Towel can be installed as a Visual Studio 2012 template. Just click `File` | `New Project` and choose `ASP.NET MVC 4 Web Application`. Then select the 'Hot Towel Single Page Application" template and run!

Installing via the NuGet Package

Hot Towel is also a NuGet package that augments an existing empty ASP.NET MVC project. Just install using Nuget and then run!

```
Install-Package HotTowel
```

How Do I Build On Hot Towel?

Simply start adding code!

1. Add your own server-side code, preferably Entity Framework and WebAPI (which really shine with Breeze.js)
2. Add views to the `App/views` folder
3. Add viewmodels to the `App/viewmodels` folder
4. Add HTML and Knockout data bindings to your new views
5. Update the navigation routes in `shell.js`

Walkthrough of the HTML/JavaScript

Views/HotTowel/index.cshtml

index.cshtml is the starting route and view for the MVC application. It contains all the standard meta tags, css links, and JavaScript references you would expect. The body contains a single `<div>` which is where all of the content (your views) will be placed when they are requested. The `@Scripts.Render` uses Require.js to run the entrance point for the application's code, which is contained in the `main.js` file. A splash screen is provided to demonstrate how to create a splash screen while your app loads.

```
<body>
    <div id="applicationHost">
        @Html.Partial("_splash")
    </div>

    @Scripts.Render("~/scripts/vendor")
        <script type="text/javascript" src="~/App/durandal/amd/require.js"
            data-main="@Url.Content("~/App/main")"></script>
</body>
```

App/main.js

The `main.js` file contains the code that will run as soon as your app is loaded. This is where you want to define your navigation routes, set your start up views, and perform any setup/bootstrapping such as priming your application's data.

The `main.js` file defines several of durandal's modules to help the application kick start. The define statement helps resolve the modules dependencies so they are available for the function. First the debugging messages are enabled, which send messages about what events the application is performing to the console window. The app.start code tells durandal framework to start the application. The conventions are set so that durandal knows all views and viewmodels are contained in the same named folders, respectively. Finally, the `app.setRoot` kicks loads the `shell` using a predefined `entrance` animation.

```
define(['durandal/app',
        'durandal/viewLocator',
        'durandal/system',
        'durandal/plugins/router'],
    function (app, viewLocator, system, router) {

    // Enable debug message to show in the console
    system.debug(true);

    app.start().then(function () {
        router.useConvention();
        viewLocator.useConvention();
        //Show the app by setting the root view model for our application.
        app.setRoot('viewmodels/shell', 'entrance');
    });
});
```

Views

Views are found in the `App/views` folder.

shell.html

The `shell.html` contains the master layout for your HTML. All of your other views will be composed somewhere in side of your `shell` view. Hot Towel provides a `shell` with three such regions: a header, a content area, and a footer. Each of these regions is loaded with contents form other views when requested.

The `compose` bindings for the header and footer are hard coded in Hot Towel to point to the `nav` and `footer` views, respectively. The compose binding for the section `#content` is bound to the `router` module's active item. In other words, when you click a navigation link it's corresponding view is loaded in this area.

```
<div>
    <header>
        <!--ko compose: {view: 'nav'} --><!--/ko-->
    </header>
     <section id="content" class="main container-fluid">
        <!--ko compose: {model: router.activeItem,
            afterCompose: router.afterCompose,
            transition: 'entrance'} -->
        <!--/ko-->
    </section>
    <footer>
        <!--ko compose: {view: 'footer'} --><!--/ko-->
    </footer>
</div>
```

nav.html

The `nav.html` contains the navigation links for the SPA. This is where the menu structure can be placed, for example. Often this is data bound (using Knockout) to the `router` module to display the navigation you defined in the `shell.js`. Knockout looks for the data-bind attributes and binds those to the `shell` viewmodel to display the navigation routes and to show a progressbar (using Twitter Bootstrap) if the `router` module is in the middle of navigating from one view to another (see `router.isNavigating`).

```
<nav class="navbar navbar-fixed-top">
    <div class="navbar-inner">
        <a class="brand" href="/">
            <span class="title">Hot Towel SPA</span>
        </a>
        <div class="btn-group" data-bind="foreach: router.visibleRoutes">
            <a data-bind="css: { active: isActive }, attr: { href: hash }, text: name"
                class="btn btn-info" href="#"></a>
        </div>
        <div class="loader pull-right" data-bind="css: { active: router.isNavigating }">
            <div class="progress progress-striped active page-progress-bar">
                <div class="bar" style="width: 100px;"></div>
            </div>
        </div>
    </div>
</nav>
```

home.html and details.html

These views contain HTML for custom views. When the `home` link in the `nav` view's menu is clicked, the `home` view will be placed in the content area of the `shell` view. These views can be augmented or replaced with your own custom views.

footer.html

The `footer.html` contains HTML that appears in the footer, at the bottom of the `shell` view.

ViewModels

ViewModels are found in the `App/viewmodels` folder.

shell.js

The `shell` viewmodel contains properties and functions that are bound to the `shell` view. Often this is where the menu navigation bindings are found (see the `router.mapNav` logic).

```
define(['durandal/system', 'durandal/plugins/router', 'services/logger'],
    function (system, router, logger) {
        var shell = {
            activate: activate,
            router: router
        };

        return shell;

        function activate() {
            return boot();
        }

        function boot() {
            router.mapNav('home');
            router.mapNav('details');
            log('Hot Towel SPA Loaded!', null, true);
            return router.activate('home');
        }

        function log(msg, data, showToast) {
            logger.log(msg, data, system.getModuleId(shell), showToast);
        }
    });
```

home.js and details.js

These viewmodels contain the properties and functions that are bound to the `home` view. it also contains the presentation logic for the view, and is the glue between the data and the view.

```
define(['services/logger'], function (logger) {
    var vm = {
        activate: activate,
        title: 'Home View'
    };

    return vm;

    function activate() {
        logger.log('Home View Activated', null, 'home', true);
        return true;
    }
});
```

Services

Services are found in the App/services folder. Ideally your future services such as a dataservice module, that is responsible for getting and posting remote data, could be placed.

logger.js

Hot Towel provides a `logger` module in the services folder. The `logger` module is ideal for logging messages to the console and to the user in pop up toasts.

ASP.NET WebHooks overview

4/6/2020 • 3 minutes to read • Edit Online

WebHooks is a lightweight HTTP pattern providing a simple pub/sub model for wiring together Web APIs and SaaS services. When an event happens in a service, a notification is sent in the form of an HTTP POST request to registered subscribers. The POST request contains information about the event which makes it possible for the receiver to act accordingly.

Because of their simplicity, WebHooks are already exposed by a large number of services including Dropbox, GitHub, Bitbucket, MailChimp, PayPal, Slack, Stripe, Trello, and many more. For example, a WebHook can indicate that a file has changed in Dropbox, or a code change has been committed in GitHub, or a payment has been initiated in PayPal, or a card has been created in Trello. The possibilities are endless!

Microsoft ASP.NET WebHooks makes it easier to both send and receive WebHooks as part of your ASP.NET application:

- On the receiving side, it provides a common model for receiving and processing WebHooks from any number of WebHook providers. It comes out of the box with support for Dropbox, GitHub, Bitbucket, MailChimp, PayPal, Pusher, Salesforce, Slack, Stripe, Trello,WordPress and Zendesk but it is easy to add support for more.
- On the sending side it provides support for managing and storing subscriptions as well as for sending event notifications to the right set of subscribers. This allows you to define your own set of events that subscribers can subscribe to and notify them when things happens.

The two parts can be used together or apart depending on your scenario. If you only need to receive WebHooks from other services then you can use just the receiver part; if you only want to expose WebHooks for others to consume, then you can do just that.

The code targets ASP.NET Web API 2 and ASP.NET MVC 5 and is available as OSS on GitHub.

WebHooks Overview

WebHooks is a pattern which means that it varies how it is used from service to service but the basic idea is the same. You can think of WebHooks as a simple pub/sub model where a user can subscribe to events happening elsewhere. The event notifications are propagated as HTTP POST requests containing information about the event itself.

Typically the HTTP POST request contains a JSON object or HTML form data determined by the WebHook sender including information about the event causing the WebHook to trigger. For example, a WebHook POST request body from GitHub looks like this as a result of a new issue being opened in a particular repository:

```
{
  "action": "opened",
  "issue": {
      "url": "https://api.github.com/repos/octocat/Hello-World/issues/1347",
      "number": 1347,
      ...
  },
  "repository": {
      "id": 1296269,
      "full_name": "octocat/Hello-World",
      "owner": {
          "login": "octocat",
          "id": 1
          ...
      },
      ...
  },
  "sender": {
      "login": "octocat",
      "id": 1,
      ...
  }
}
```

To ensure that the WebHook is indeed from the intended sender, the POST request is secured in some way and then verified by the receiver. For example, GitHub WebHooks includes an *X-Hub-Signature* HTTP header with a hash of the request body which is checked by the receiver implementation so you don't have to worry about it.

The WebHook flow generally goes something like this:

- The WebHook sender exposes events that a client can subscribe to. The events describe observable changes to the system, for example that a new data item has been inserted, that a process has completed, or something else.
- The WebHook receiver subscribes by registering a WebHook consisting of four things:
  1. A URI for where the event notification should be posted in the form of an HTTP POST request;
  2. A set of filters describing the particular events for which the WebHook should be fired;
  3. A secret key which is used to sign the HTTP POST request;
  4. Additional data which is to be included in the HTTP POST request. This can for example be additional HTTP header fields or properties included in the HTTP POST request body.
- Once an event happens, the matching WebHook registrations are found and HTTP POST requests are submitted. Typically, the generation of the HTTP POST requests are retried several times if for some reason the recipient is not responding or the HTTP POST request results in an error response.

WebHooks Processing Pipeline

The Microsoft ASP.NET WebHooks processing pipeline for incoming WebHooks looks like this:

The two key concepts here are *Receivers* and *Handlers*:

- *Receivers* are responsible for handling the particular flavor of WebHook from a given sender and for enforcing security checks to ensure that the WebHook request indeed is from the intended sender.
- *Handlers* are typically where user code runs processing the particular WebHook.

In the following nodes these concepts are described in more details.

ASP.NET WebHooks source code and NuGet packages

4/6/2020 • 2 minutes to read • Edit Online

Microsoft ASP.NET WebHooks is part of the Microsoft ASP.NET family of modules and is hosted as an Open Source Project on GitHub. This means that we accept contributions, but please look at the Contribution Guidelines before submitting a pull request.

This online documentation which you are reading now is also hosted as Open Source on GitHub and also accepts contributions.

NuGet packages

The NuGet packages are divided into three parts:

- Common: A common package that is shared between senders and receivers.
- Sender: A set of packages supporting sending your own WebHooks to others. The functionality for sending WebHooks is described in more detail in Sending WebHooks.
- Receivers: A set of packages supporting receiving WebHooks from others. The functionality for receiving WebHooks is described in more detail in Receiving WebHooks.

ASP.NET WebHooks - receiving and processing

4/6/2020 • 2 minutes to read • Edit Online

- WebHook Receivers
- Processing WebHooks
- Receiver Dependencies

ASP.NET WebHooks receivers

4/6/2020 • 2 minutes to read • Edit Online

Receiving WebHooks depends on who the sender is. Sometimes there are additional steps registering a WebHook verifying that the subscriber is really listening. Some WebHooks provide a push-to-pull model where the HTTP POST request only contains a reference to the event information which is then to be retrieved independently. Often the security model varies quite a bit.

The purpose of Microsoft ASP.NET WebHooks is to make it both simpler and more consistent to wire up your API without spending a lot of time figuring out how to handle any particular variant of WebHooks.

A WebHook receiver is responsible for accepting and verifying WebHooks from a particular sender. A WebHook receiver can support any number of WebHooks, each with their own configuration. For example, the GitHub WebHook receiver can accept WebHooks from any number of GitHub repositories.

WebHook Receiver URIs

By installing Microsoft ASP.NET WebHooks you get a general WebHook controller which accepts WebHook requests from an open-ended number of services. When a request arrives, it picks the appropriate receiver that you have installed for handling a particular WebHook sender.

The URI of this controller is the WebHook URI that you register with the service and is of the form:

```
https://<host>/api/webhooks/incoming/<receiver>/{id}
```

For security reasons, many WebHook receivers require that the URI is an *https* URI and in some cases it must also contain an additional query parameter which is used to enforce that only the intended party can send WebHooks to the URI above.

The `<receiver>` component is the name of the receiver, for example `github` or `slack`.

The *{id}* is an optional identifier which can be used to identify a particular WebHook receiver configuration. This can be used to register N WebHooks with a particular receiver. For example, the following three URIs can be used to register for three independent WebHooks:

```
https://<host>/api/webhooks/incoming/github
https://<host>/api/webhooks/incoming/github/12345
https://<host>/api/webhooks/incoming/github/54321
```

Installing a WebHook Receiver

To receive WebHooks using Microsoft ASP.NET WebHooks, you first install the Nuget package for the WebHook provider or providers you want to receive WebHooks from. The Nuget packages are named Microsoft.AspNet.WebHooks.Receivers.* where the last part indicates the service supported. For example

Microsoft.AspNet.WebHooks.Receivers.GitHub provides support for receiving WebHooks from GitHub and Microsoft.AspNet.WebHooks.Receivers.Custom provides support for receiving WebHooks generated by ASP.NET WebHooks.

Out of the box you can find support for Dropbox, GitHub, MailChimp, PayPal, Pusher, Salesforce, Slack, Stripe, Trello, and WordPress but it is possible to support any number of other providers.

Configuring a WebHook Receiver

WebHook Receivers are configured through the IWebHookReceiverConfig inteface and particular implementations of that interface can be registered using any dependency injection model. The default implementation uses Application Settings which can either be set in the Web.config file, or, if using Azure Web Apps, can be set through the Azure Portal.

The format for Application Setting keys is as follows:

```
MS_WebHookReceiverSecret_<receiver>
```

The value is a comma-separated list of values matching the *{id}* values for which WebHooks have been registered, for example:

```
MS_WebHookReceiverSecret_GitHub = <secret1>, 12345=<secret2>, 54321=<secret3>
```

Initializing a WebHook Receiver

WebHook Receivers are initialized by registering them, typically in the *WebApiConfig* static class, for example:

```
namespace WebHookReceivers
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            // Web API configuration and services

            // Web API routes
            config.MapHttpAttributeRoutes();

            config.Routes.MapHttpRoute(
                name: "DefaultApi",
                routeTemplate: "api/{controller}/{id}",
                defaults: new { id = RouteParameter.Optional }
            );

            // Load receivers
            config.InitializeReceiveGitHubWebHooks();
        }
    }
}
```

ASP.NET WebHooks handlers

4/6/2020 • 2 minutes to read • Edit Online

Once WebHooks requests has been validated by a WebHook receiver, it is ready to be processed by user code. This is where *handlers* come in. Handlers derive from the IWebHookHandler interface but typically uses the WebHookHandler class instead of deriving directly from the interface.

A WebHook request can be processed by one or more handlers. Handlers are called in order based on their respective *Order* property going from lowest to highest where Order is a simple integer (suggested to be between 1 and 100):

A handler can optionally set the *Response* property on the WebHookHandlerContext which will lead the processing to stop and the response to be sent back as the HTTP response to the WebHook. In the case above, Handler C won't get called because it has a higher order than B and B sets the response.

Setting the response is typically only relevant for WebHooks where the response can carry information back to the originating API. This is for example the case with Slack WebHooks where the response is posted back to the channel where the WebHook came from. Handlers can set the Receiver property if they only want to receive WebHooks from that particular receiver. If they don't set the receiver they are called for all of them.

One other common use of a response is to use a *410 Gone* response to indicate that the WebHook no longer is active and no further requests should be submitted.

By default a handler will be called by all WebHook receivers. However, if the *Receiver* property is set to the name of a handler then that handler will only receive WebHook requests from that receiver.

Processing a WebHook

When a handler is called, it gets a WebHookHandlerContext containing information about the WebHook request. The data, typically the HTTP request body, is available from the *Data* property.

The type of the data is typically JSON or HTML form data, but it is possible to cast to a more specific type if desired. For example, the custom WebHooks generated by ASP.NET WebHooks can be cast to the type CustomNotifications as follows:

```
public class MyWebHookHandler : WebHookHandler
{
    public MyWebHookHandler()
    {
        this.Receiver = "custom";
    }

    public override Task ExecuteAsync(string generator, WebHookHandlerContext context)
    {
        CustomNotifications notifications = context.GetDataOrDefault<CustomNotifications>();
        foreach (var notification in notifications.Notifications)
        {
            ...
        }
        return Task.FromResult(true);
    }
}
```

Queued Processing

Most WebHook senders will resend a WebHook if a response is not generated within a handful of seconds. This means that your handler must complete the processing within that time frame in order not for it to be called again.

If the processing takes longer, or is better handled separately then the WebHookQueueHandler can be used to submit the WebHook request to a queue, for example Azure Storage Queue.

An outline of a WebHookQueueHandler implementation is provided here:

```
public class QueueHandler : WebHookQueueHandler
{
    public override Task EnqueueAsync(WebHookQueueContext context)
    {

        // Enqueue WebHookQueueContext to your queuing system of choice

        return Task.FromResult(true);
    }
}
```

ASP.NET WebHooks receiver dependencies

4/6/2020 • 2 minutes to read • Edit Online

Microsoft ASP.NET WebHooks is designed with dependency injection in mind. Most dependencies in the system can be replaced with alternative implementations using a dependency injection engine.

See DependencyScopeExtensions for a list of receiver dependencies. If no dependency has been registered, a default implementation is used. See ReceiverServices for a list of default implementations.

ASP.NET WebHook senders

4/10/2020 • 2 minutes to read • Edit Online

See the blog Sending WebHooks with ASP.NET WebHooks Preview for more details.

ASP.NET WebHooks Diagnostics

4/6/2020 • 2 minutes to read • Edit Online

- Logging
- Debugging

ASP.NET WebHooks logging

4/6/2020 • 2 minutes to read • Edit Online

Microsoft ASP.NET WebHooks uses logging as a way of reporting issues and problems. By default logs are written using System.Diagnostics.Trace where they can be manged using Trace Listeners like any other log stream.

When deploying your Web Application as an Azure Web App, the logs are automatically picked up and can be managed together with any other System.Diagnostics.Trace logging. For details, please see Enable diagnostics logging for web apps in Azure App Service

In addition, logs can be obtained straight from inside Visual Studio as described in Troubleshoot a web app in Azure App Service using Visual Studio.

Redirecting Logs

Instead of writing logs to System.Diagnostics.Trace, it is possible to provide an alternate logging implementation that can log directly to a log manager such as Log4Net and NLog. Simply provide an implementation of ILogger and register it with a dependency injection engine of your choice and it will get picked up by Microsoft ASP.NET WebHooks. Please see Dependency Injection in ASP.NET Web API 2 for details.

ASP.NET WebHooks debugging

4/6/2020 • 2 minutes to read • Edit Online

Debugging in Azure

To debug your Web Application while running in Azure, please see the tutorial Troubleshoot a web app in Azure App Service using Visual Studio.

Debugging with Source and Symbols

In addition to debugging your own code, it is possible to debug directly into Microsoft ASP.NET WebHooks, and in fact all of .NET. This works regardless of whether you debug locally or remotely. First, configure Visual Studio to find the source and symbols by going to **Debug** and then **Options and Settings**. Set the options like this:

Then add a link to symbolsource.org for downloading the source and symbols. Go to the **Symbols** tab of the menu above and add the following as a symbol location:

```
http://srv.symbolsource.org/pdb/Public
```

In addition, make sure that the cache directory has a short name; otherwise the file names can get too long which will cause the symbols to not load. A sample path is:

```
C:\SymCache
```

The settings should look similar to this:

ASP.NET and Visual Studio 2017

2/20/2020 • 2 minutes to read • Edit Online

Optimize build performance for solution

Optimize build performance for solution

2/20/2020 • 2 minutes to read • Edit Online

Visual Studio 2017 15.8 or later include a menu item: **Build** > **ASP.NET Compilation** > **Optimize Build Performance for Solution**.

ASP.NET compiles its views at runtime, which means that an ASP.NET project carries with it a copy of the compiler. However on a developer machine when the copy of the compiler doesn't match Visual Studio's copy, build performance is impacted on the order of 1-3 seconds per incremental build. This feature updates your project's copy of the compiler to match Visual Studio's, which usually speeds up incremental builds.

This is applicable to ASP.NET Framework 4.7.1 or later projects only, it does not apply to ASP.NET Core.

Creating ASP.NET Web Projects in Visual Studio 2013

2/20/2020 • 22 minutes to read • Edit Online

by Tom Dykstra

This topic explains the options for creating ASP.NET web projects in Visual Studio 2013 with Update 3

Here are some of the new features for web development compared to earlier versions of Visual Studio:

- A simple UI for creating projects that offer support for multiple ASP.NET frameworks (Web Forms, MVC, and Web API).
- ASP.NET Identity, a new ASP.NET membership system that works the same in all ASP.NET frameworks and works with web hosting software other than IIS.
- The use of Bootstrap to provide responsive design and theming capabilities.
- New features for Web Forms that used to be offered only for MVC, such as automatic test project creation and an Intranet site template.

For information about how to create web projects for Azure Cloud Services or Azure Mobile Services, see Get Started with Azure Cloud Services and ASP.NET and Creating a Leaderboard App with Azure Mobile Services .NET Backend.

Prerequisites

This article applies to Visual Studio 2013 with Update 3 installed.

Web application projects versus web site projects

ASP.NET gives you a choice between two kinds of web projects: *web application projects* and *web site projects*. We recommend web application projects for new development, and this article applies only to web application projects. For more information, see Web Application Projects versus Web Site Projects in Visual Studio on the MSDN site.

Overview of web application project creation

The following steps show how to create a web project:

1. Click **New Project** in the **Start** page or in the **File** menu.
2. In the **New Project** dialog, click **Web** in the left pane and **ASP.NET Web Application** in the middle pane.

You can choose **Cloud** in the left pane to create an Azure Cloud Service, Azure Mobile Service, or Azure WebJob. This topic doesn't cover those templates.

3. In the right pane, click the **Add Application Insights to Project** check box if you want health and usage monitoring for your application. For more information, see Monitor performance in web applications.

4. Specify project **Name**, **Location**, and other options, and then click **OK**.

   The **New ASP.NET Project** dialog appears.

5. Click a template.

6. If you want to add support for additional frameworks not included in the template, click the appropriate check box. (In the example shown, you could add MVC and/or Web API to a Web Forms project.)

7. If you want to add a unit test project, click **Add unit tests**.

8. If you want a different authentication method than what the template provides by default, click **Change Authentication**.

Create a web app or virtual machine in Azure

Visual Studio includes features that make it easy to work with Azure services for hosting web applications. For example, you can do all of the following right from the Visual Studio IDE:

- Create and manage web apps or virtual machines that make your application available over the Internet.
- View logs created by the application as it runs in the cloud.
- Run in debug mode remotely while the application runs in the cloud.

- View and manage other Azure services such as SQL databases.

You can create an Azure account that includes basic services such as web apps for free, and if you are an MSDN subscriber you can activate benefits that give you monthly credits toward additional Azure services.

By default the **New ASP.NET Project** dialog box enables you to create a web app or virtual machine for a new web project. If you don't want to create a new web app or virtual machine, clear the **Host in the cloud** check box.

The check box caption might be **Host in the cloud** or **Create remote resources**, and in either case the effect is the same. If you leave the check box selected, Visual Studio creates a web app in Azure App Service by default. You can use the drop-down box to change that to a **Virtual Machine** if you prefer. If you're not already signed in to Azure, you're prompted for Azure credentials. After you sign in, a dialog box enables you to configure the resources that Visual Studio will create for your project. The following illustration shows the dialog for a web app; different options appear if you choose to create a virtual machine.

For more information about how to use this process for creating Azure resources, see Get Started with Azure and ASP.NET and Creating a virtual machine for a web site with Visual Studio.

The remainder of this article provides more information about the available templates and their options. The article also introduces Bootstrap, the layout and theming framework used in the templates.

Visual Studio 2013 Web Project Templates

Visual Studio uses templates to create web projects. A project template can create files and folders in the new project, install NuGet packages, and provide sample code for a rudimentary working application. Templates implement the latest web standards and are intended to demonstrate best practices for how to use ASP.NET technologies as well as give you a jump start on creating your own application.

Visual Studio 2013 provides the following choices for web project templates for projects that target .NET 4.5 or later versions of the .NET framework:

- Empty template
- Web Forms template
- MVC template
- Web API template
- Single Page Application template
- Azure Mobile Service template
- Visual Studio 2012 Templates

You can also install a Visual Studio extension that provides a Facebook template.

For information about how to create projects that target .NET 4, see Visual Studio 2012 Templates later in this topic.

For information about how to create ASP.NET applications for mobile clients, see Mobile Support in ASP.NET.

Empty Template

The Empty template provides the bare minimum folders and files for an ASP.NET web app, such as a project file (*.csproj* or *.vbproj*) and a *Web.config* file. You can add support for Web Forms, MVC, and/or Web API by using the check boxes under the **Add folders and core references for:** label.

For the Empty template no authentication options are available. Authentication functionality is implemented in sample applications, and the Empty template does not create a sample application.

Web Forms Template

The Web Forms framework provides the following features that let you rapidly build web sites that are rich in UI and data access features:

- A WYSIWYG designer in Visual Studio.
- Server controls that render HTML and that you can customize by setting properties and styles.
- A rich assortment of controls for data access and data display.
- An event model that exposes events which you can program like you would program a client application such as WPF.
- Automatic preservation of state (data) between HTTP requests.

In general, creating a Web Forms application requires less programming effort than creating the same application by using the ASP.NET MVC framework. However, Web Forms is not just for rapid application development. There are many complex commercial applications and frameworks built on top of Web Forms.

Because a Web Forms page and the controls on the page automatically generate much of the markup that's sent to the browser, you don't have the kind of fine-grained control over the HTML that ASP.NET MVC offers. The declarative model for configuring pages and controls minimizes the amount of code you have to write but hides some of the behavior of HTML and HTTP. For example, it's not always possible to specify exactly what markup might be generated by a control.

The Web Forms framework doesn't lend itself as readily as ASP.NET MVC to patterns-based development practices such as test-driven development, separation of concerns, inversion of control, and dependency injection. If you want to write code factored that way, you can; it's just not as automatic as it is in the ASP.NET MVC framework. The ASP.NET Web Forms MVP project shows an approach that facilitates separation of concerns and testability while maintaining the rapid development that Web Forms was built to deliver. Microsoft SharePoint is built on Web Forms MVP.

The Web Forms template creates a sample Web Forms application that uses Bootstrap to provide responsive design and theming features. The following illustration shows the home page.

For more information about Web Forms, see ASP.NET Web Forms. For information about what the Web Forms template does for you, see Building a basic Web Forms application using Visual Studio 2013.

MVC Template

ASP.NET MVC was designed to facilitate patterns-based development practices such as test-driven development, separation of concerns, inversion of control, and dependency injection. The framework encourages separating the business logic layer of a web application from its presentation layer. By dividing the application into models (M), views (V), and controllers (C), ASP.NET MVC can make it easier to manage complexity in larger applications.

With ASP.NET MVC, you work more directly with HTML and HTTP than in Web Forms. For example, Web Forms can automatically preserve state between HTTP requests, but you have to code that explicitly in MVC. The advantage of the MVC model is that it enables you to take complete control over exactly what your application is doing and how it behaves in the web environment. The disadvantage is that you have to write more code.

MVC was designed to be extensible, providing power developers the ability to customize the framework for their application needs. In addition, the ASP.NET MVC source code is available under an OSI license.

The MVC template creates a sample MVC 5 application that uses Bootstrap to provide responsive design and theming features. The following illustration shows the home page.

For more information about MVC, see ASP.NET MVC. For information about how to select the MVC 4 template, see Visual Studio 2012 templates later in this article.

Web API Template

The Web API template creates a sample web service based on Web API, including API help pages based on MVC.

ASP.NET Web API is a framework that makes it easy to build HTTP services that reach a broad range of clients, including browsers and mobile devices. ASP.NET Web API is an ideal platform for building RESTful services on the .NET Framework.

The Web API template creates a sample web service. The following illustrations show sample help pages.

http://localhost:18:
ASP.NET Web API Help Page
ASP.NET Web API Help Page
Introduction
Provide a general description of your APIs here.
Values
API
Description
GET api/Values
Documentation for 'Get'.
GET api/Values/{id}
Documentation for 'Get'.
POST api/Values
Documentation for 'Post'.
PUT api/Values/{id}
Documentation for 'Put'.
DELETE api/Values/{id}
Documentation for 'Delete'.

For more information about Web API, see ASP.NET Web API.

Single Page Application Template

The Single Page Application (SPA) template creates a sample application that uses JavaScript, HTML 5, and KnockoutJS on the client, and ASP.NET Web API on the server.

The only authentication option for the SPA template is Individual User Accounts.

The following illustration shows the initial state of the sample application that the SPA template builds.

For information about how to create an application by using the SPA template, see Web API - External Authentication Services.

For more information about ASP.NET Single Page Applications, and about additional SPA templates that use JavaScript frameworks other than KnockoutJS, see the following resources:

- ASP.NET Single Page Application.
- Understanding Security Features in the SPA Template for VS2013 RC
- Single-Page Applications: Build Modern, Responsive Web Apps with ASP.NET

Facebook Template

You can install a Visual Studio extension that provides a Facebook template. This template creates a sample application that is designed to run inside the Facebook web site. It is based on ASP.NET MVC and uses Web API for real-time update functionality.

No authentication options are available for the Facebook template because Facebook applications run within the Facebook site and rely on Facebook's authentication.

For more information about ASP.NET Facebook applications, see Updating the MVC Facebook API.

Visual Studio 2012 Templates

The Visual Studio 2013 web project creation dialog does not provide access to some templates that were available in Visual Studio 2012. If you want to use one of these templates, you can click the Visual Studio 2012 node in the left pane of the Visual Studio New Project dialog box.

The **Visual Studio 2012** node lets you choose the following web templates that you don't have access to in the default list of templates for Visual Studio 2013:

- ASP.NET MVC 4 Web Application
- ASP.NET Dynamic Data Entities Web Application
- ASP.NET AJAX Server Control
- ASP.NET AJAX Server Control Extender
- ASP.NET Server Control

Bootstrap in the Visual Studio 2013 web project templates

The Visual Studio 2013 project templates use Bootstrap, a layout and theming framework created by Twitter. Bootstrap uses CSS3 to provide responsive design, which means layouts can dynamically adapt to different browser window sizes. For example, in a wide browser window the home page created by the Web Forms template looks like the following illustration:

Make the window narrower, and the horizontally arranged columns move into vertical arrangement:

Narrow the window a little more, and the horizontal top menu turns into an icon that you can click to expand into a vertically oriented menu:

http://localhost:54168/Home/Index

You can also use Bootstrap's theming feature to easily effect a change in the application's look and feel. For example, you can do the following steps to change the theme.

1. In your browser, go to http://Bootswatch.com, choose a theme, and then click **Download**. (This downloads *bootstrap.min.css* by default; if you want to examine the CSS code, get *bootstrap.css* instead of the minified version.)
2. Copy the contents of the downloaded CSS file.
3. In Visual Studio, create a new **Style Sheet** file named *bootstrap-theme.css* in the *Content* folder and paste the downloaded CSS code into it.
4. Open *App_Start/Bundle.config* and change *bootstrap.css* to *bootstrap-theme.css*.

Run the project again, and the application has a new look. The following illustration shows the effect of the Amelia theme:

Many Bootstrap themes are available, both free and premium versions. Bootstrap also offers a wide variety of UI components, such as drop-downs, button groups, and icons. For more information about Bootstrap, see the Bootstrap site.

If you use the Web Forms designer in Visual Studio, note that the designer doesn't support CSS3, so it doesn't accurately show all the effects of Bootstrap themes or responsive layout changes. However, the Web Forms pages will display correctly when viewed with a browser.

Adding Support for Additional Frameworks

When you select a template, the check box for the framework(s) used by the template is automatically selected. For example, if you select the **Web Forms** template, the **Web Forms** check box is selected and you can't clear it.

You can select the check box for a framework that isn't included in the template in order to add support for that framework when the project is created. For example, to enable the use of Web Forms *.aspx* pages when you've

selected the MVC template, select the **Web Forms** check box. Or to enable MVC when you're using the Web Forms template, click the **MVC** check box. Adding a framework enables design-time as well as run-time support. For example, if you add MVC support to a Web Forms project, you will be able to scaffold controllers and views.

If you combine Web Forms and MVC in a project and enable Friendly URLs in Web Forms, there might be unexpected routing problems where one URL has multiple possible targets. The routes that are defined first will take precedence. For example, if you have a `Home` controller and a *Home.aspx* page, the `http://contoso.com/home` URL will go to *Home.aspx* if you call the `EnableFriendlyUrls` method before you call the `MapRoute` method in *RouteConfig.cs*, or the same URL will go to the default view for your `Home` controller if you call `MapRoute` before `EnableFriendlyUrls`.

Adding a framework does not add any sample application functionality. For example, if you add Web Forms support when you've selected the MVC template, no *Default.aspx* home page file is created. Only the folders, files, and references required to support the framework are added. For that reason, adding frameworks doesn't change authentication options, which are implemented by code in sample applications created by the templates. For example, if you select the Empty template and add Web Forms or MVC support, the **Configure Authentication** button will still be disabled.

The following sections describe briefly the effect of each check box.

Add Web Forms Support

Creates empty *App_Data* and *Models* folders and a *Global.asax* file. These are already created by all templates other than the Empty template, so selecting the Web Forms check box makes no difference for other templates.

The Web Forms template enables Friendly URLs by default, but when you add Web Forms support to other templates by selecting the Web Forms check box Friendly URLs are not automatically enabled.

Add MVC Support

Installs MVC, Razor, and WebPages NuGet packages, creates empty *App_Data*, *Controllers*, *Models*, and *Views* folders, creates *App_Start* folder with *RouteConfig.cs* file, and creates *Global.asax* file.

Add Web API Support

Installs WebApi and Newtonsoft.Json NuGet packages, creates empty *App_Data*, *Controllers*, and *Models* folders, creates *App_Start* folder with *WebApiConfig.cs* file, and creates *Global.asax* file.

Authentication Methods

Visual Studio 2013 offers several authentication options for the Web Forms, MVC, and Web API templates:

- No Authentication
- Individual User Accounts (ASP.NET Identity, formerly known as ASP.NET membership)
- Organizational Accounts (Windows Server Active Directory or Azure Active Directory)
- Windows Authentication (Intranet)

No Authentication

If you select **No Authentication**, the sample application will contain no web pages for logging in, no UI indicating who is logged in, no entity classes for a membership database, and no connection string for a membership database.

Individual User Accounts

If you select **Individual User Accounts**, the sample application will be configured to use ASP.NET Identity (formerly known as ASP.NET membership) for user authentication. ASP.NET Identity enables a user to register an account, by creating a username and password on the site or by signing in with social providers such as Facebook, Google, Microsoft Account, or Twitter. The default data store for user profiles in ASP.NET Identity is a SQL Server LocalDB database, which you can deploy to SQL Server or Azure SQL Database for the production site.

In Visual Studio 2013 these features are the same as in Visual Studio 2012, but the underlying code for the ASP.NET membership system has been rewritten. Advantages of the new code base include the following:

- The new membership system is based on OWIN rather than the ASP.NET Forms Authentication module. This means that you can use the same authentication mechanism whether you're using Web Forms or MVC in IIS, or you're self-hosting Web API or SignalR.
- The new membership database is managed by Entity Framework Code First, and all of the tables are represented by entity classes that you can modify. This means that you can easily customize the database schema and profile-related web UI to fit your own needs, and you can easily deploy your updates using Code First Migrations.

The new membership system is implemented automatically in the new templates, and it can be implemented manually in any project that targets .NET 4.5 or later.

ASP.NET Identity is a good choice if you are creating an Internet web site which is mainly for external customers. If your organization uses Active Directory or Office 365 and you want to create a project that enables single-sign-on for employees and business partners, the **Organizational Accounts** option might be a better choice.

For more information about the Individual User Accounts option, see the following resources:

- www.asp.net/identity. Documentation about ASP.NET Identity on the ASP.NET web site.
- Create an ASP.NET MVC 5 App with Facebook and Google OAuth2 and OpenID Sign-on. Also shows how to customize user profile data.
- Web API - External Authentication Services
- Adding External Logins to your ASP.NET application in Visual Studio 2013

Organizational Accounts

If you select **Organizational Accounts**, the sample application will be configured to use Windows Identity Foundation (WIF) for authentication based on user accounts in Azure Active Directory (Azure AD, which includes Office 365) or Windows Server Active Directory. For more information, see Organizational account authentication

options later in this topic.

Windows Authentication

If you select **Windows Authentication**, the sample application will be configured to use the Windows Authentication IIS module for authentication. The application will display the domain and user ID of the Active directory or local machine account that is logged into Windows but won't include user registration or log-in UI. This option is intended for Intranet web sites.

Alternatively, you can create an Intranet site that uses AD authentication by choosing the On-Premises option under Organizational Accounts. The On-Premises option uses Windows Identity Foundation (WIF) instead of the Windows Authentication module. Some additional steps are required in order to set up the On-Premises option, but WIF enables features that aren't available with the Windows Authentication module. For example, with WIF you can configure application access in Active Directory and query directory data.

Organizational account authentication options

The **Configure Authentication** dialog gives you several options for Azure Active Directory (Azure AD, which includes Office 365) or Windows Server Active Directory (AD) account authentication:

- Cloud - Single Organization (Azure AD, or AD using directory integration with Azure AD)
- Cloud - Multi Organization (Azure AD, or AD using directory integration with Azure AD)
- On-Premises (AD)

If you want to try one of the Azure AD options but don't have an account yet, click here to sign up for a Azure AD account.

> **NOTE**
>
> If you choose one of the Azure AD options, your project requires a database and you have to sign in to a global administrator account for your Azure AD tenant. Enter the name and password for an organizational account (for example, admin@contoso.onmicrosoft.com) that has administrative permissions for your Azure AD tenant.
>
> **Don't enter credentials for a Microsoft account (for example, contoso@hotmail.com) in the sign-in dialog box.**

Cloud - Single Organization Authentication

Choose this option if you want to enable authentication for user accounts that are defined in one Azure AD tenant. For example, the site is contoso.com and it will be made available to employees of the Contoso Company who are in the contoso.onmicrosoft.com tenant. You won't be able to configure Azure AD to allow users from other tenants to access the application.

Domain

Enter the Azure AD domain that you want to set up the application in, for example: `contoso.onmicrosoft.com`. If you have a custom domain, such as `contoso.com` instead of `contoso.onmicrosoft.com`, you can enter that here.

Access Level

If the application needs to query or update directory information by using the Graph API, choose **Single Sign-On, Read Directory Data** or **Single Sign-On, Read and Write Directory Data**. Otherwise, choose **Single Sign-On**. For more information, see Application Access Levels and Using the Graph API to Query Azure AD.

Application ID URI

By default, the template creates an application ID URI for you by appending the project name to the Azure AD domain. For example, if the project name is `Example` and the domain is `contoso.onmicrosoft.com`, the application ID URI becomes `https://contoso.onmicrosoft.com/Example`. If you want to manually specify the application ID URI, expand the **More Options** section and enter the application ID URI in the text box. The application ID URI must begin with `https://`.

By default, if an application that is already provisioned in Azure AD has the same application ID URI as the one that Visual Studio is using for the project, the project will be connected to the existing application instead of provisioning a new one. If you want a new application to be provisioned in that case, clear the **Overwrite the application entry if one with the same ID already exists** check box.

If the **Overwrite** check box is cleared, and Visual Studio finds an existing application with the same application ID URI, it creates a new URI by appending a number to the URI it was going to use. For example, suppose the project name is `Example`, you leave the text box blank, you clear the **Overwrite** check box, and the Azure AD tenant already has an application with the URI `https://contoso.onmicrosoft.com/Example`. In that case, a new application

will be provisioned with an application ID URI like `https://contoso.onmicrosoft.com/Example_20130619330903`.

Provisioning the application in Azure AD

In order to provision the application in Azure AD or connect the project to an existing application, Visual Studio needs the credentials of a global administrator for the domain. When you click **OK** in the **Configure Authentication** dialog box, you are prompted for the user name and password of a global administrator for the domain you specified. Later, when you click **Create Project** in the **New ASP.NET Project** dialog, Visual Studio provisions the application in Azure AD. Note that as part of this process Visual Studio embeds client secret values in the Web.config file that expire one year after creation.

For information about how to create applications that use **Cloud - Single Organization** authentication, see the following resources:

- Azure Authentication
- Adding Sign-On to Your Web Application Using Azure AD
- Developing ASP.NET Apps with Azure Active Directory
- Secure ASP.NET Web API with Azure AD and Microsoft OWIN Components

The tutorials have not yet been updated for Visual Studio 2013; some of what the tutorials direct you to do manually is automated in Visual Studio 2013.

Cloud - Multi Organization Authentication

Choose this option if you want to enable authentication for user accounts that are defined in multiple Azure AD tenants. For example, the site is contoso.com and it will be made available to employees of the Contoso Company who are in the contoso.onmicrosoft.com tenant, and employees of the Fabrikam Company who are in the fabrikam.onmicrosoft.com tenant.

The settings that you enter and the application provisioning step are similar to single organization authentication.

For information about how to create applications that use **Cloud - Multi Organization** authentication, see the following resources:

- Easy Web App Integration with Azure Active Directory, ASP.NET & Visual Studio on the Active Directory Team blog.
- Developing Multi-Tenant Web Applications with Azure AD tutorial. The tutorial hasn't yet been updated for Visual Studio 2013; some of what the tutorial directs you to do manually is automated in Visual Studio 2013.
- You Have to Sign Up With Your Own Multiple Organizations ASP.NET App Before You Can Sign In. Blog by Vittorio Bertocci that explains how to resolve a common problem people encounter when creating a project that uses multi-organization authentication.

On-Premises Organizational Authentication

Choose this option if you want to enable authentication for user accounts that are defined in Windows Server Active Directory (AD), and you don't want to use Azure AD. You can use this option to create an Intranet site or an Internet site. For an Internet site, use Active Directory Federation Services (ADFS) to provide access to AD. For more information, see Use the On-Premises Organizational Authentication Option (ADFS) With ASP.NET in Visual Studio 2013.

For an Intranet site, as an alternative you can choose Windows Authentication instead of this option. For the Windows Authentication option you don't have to provide a metadata document URL. However, Windows Authentication does not give you the ability to control application access in Active Directory or to query directory data.

On-Premises Authority

Enter a URL that points to the metadata document. The metadata document contains the coordinates of the authority. The application will use those coordinates to drive the web sign-on flow.

Application ID URI

Provide a unique URI that AD can use to identify this application, or leave blank to let Visual Studio create one.

Next steps

This document has provided some basic help for creating a new ASP.NET web project in Visual Studio 2013. For more information about using for Visual Studio for web development, see https://www.asp.net/visual-studio/.

ASP.NET Scaffolding in Visual Studio 2013

2/20/2020 • 3 minutes to read • Edit Online

by Tom FitzMacken

> ASP.NET Scaffolding is a new feature that is included in Visual Studio 2013.

Overview

ASP.NET Scaffolding is a code generation framework for ASP.NET Web applications. Visual Studio 2013 includes pre-installed code generators for MVC and Web API projects. You add scaffolding to your project when you want to quickly add code that interacts with data models. Using scaffolding can reduce the amount of time to develop standard data operations in your project.

By default, Visual Studio 2013 does not support generating code for a Web Forms project, but you can use scaffolding with Web Forms by either adding MVC dependencies to the project or installing an extension. Both approaches are shown below.

Visual Studio 2013 Update 2 (currently RC) provides the ability to extend ASP.NET Scaffolding to meet the requirements of your scenario. With this functionality, you can create a customized scaffolding template and add it to Add New Scaffold dialog. Within the customized template, you specify the code that is generated when adding a scaffolded item. For more information, see Creating a Custom Scaffolder for Visual Studio.

Prerequisites

To use ASP.NET Scaffolding, you must have:

- Microsoft Visual Studio 2013
- Web Developer Tools (part of default Visual Studio 2013 installation)
- ASP.NET Web Frameworks and Tools 2013 (part of default Visual Studio 2013 installation)

Add a scaffolded item to MVC or Web API

To add a scaffold, right-click either the project or a folder within the project, and select **Add – New Scaffolded Item**, as shown in the following image.

From the **Add Scaffold** window, select the type of scaffold to add.

The **Add Controller** window gives you the opportunity to select options for generating the controller, including whether you want to use the new async features from Entity Framework 6.

The relevant classes and pages are created for your scenario. For example, the following image shows the MVC controller and views that were created through scaffolding for a model class named Movies.

Add a scaffolded item to Web Forms

To add scaffolding that generates Web Forms code, you must either install an extension to Visual Studio or add MVC dependencies. Both approaches are shown below, but you only need to do one of these approaches.

Web Forms Scaffolding Extension

You can install a Visual Studio extension that enable you to use scaffolding with a Web Forms project. In Visual Studio, select **Tools** and then **Extensions and Updates**. From this dialog search the Visual Studio Gallery for **Web Forms Scaffolding**.

For more information, see Web Forms Scaffolding.

MVC Dependencies

To add MVC dependencies, select **Add - New Scaffolded Item**. In the Add Scaffold window, select **MVC Dependencies**, as shown below.

There are two options for scaffolding MVC; Minimal and Full. If you select Minimal, only the NuGet packages and references for ASP.NET MVC are added to your project. If you select the Full option, the Minimal dependencies are added, as well as the required content files for an MVC project. To easily use scaffolding, select Full dependencies.

After adding the dependencies, you will see a **readme.txt** file. Carefully follow the instructions in this file to ensure that your project works correctly.

When you have completed the steps in the readme.txt file, you can add a new scaffolded item as shown in the previous section about MVC and Web API. The automatically-generated views and controller will function correctly within your project.

Tutorials

To create a customized scaffolder, see Creating a Custom Scaffolder for Visual Studio.

To customize the generated files, see How to customize the generated files from the New Scaffolded Item dialog.

For an example of using scaffolding with **Database First development**, see EF Database First with ASP.NET MVC.

For an example of using scaffolding in an **MVC** project, see Getting Started with ASP.NET MVC 5.

For an example of using scaffolding in a **Web API** project, see Create a REST API with Attribute Routing in Web API 2.

Using Browser Link in Visual Studio 2013

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Browser Link is a new feature in Visual Studio 2013 that creates a communication channel between the development environment and one or more web browsers. You can use Browser Link to refresh your web application in several browsers at once, which is useful for cross-browser testing.

- Browser Refresh
- Viewing the Browser Link Dashboard
- Enabling Browser Link for Static HTML Files
- Disabling Browser Link
- How Does It Work?

Browser Refresh

With Browser Refresh, you can refresh multiple browsers that are connected to Visual Studio through Browser Link.

To use Browser Refresh, first create an ASP.NET application, using any of the project templates. Debug the application by pressing F5 or clicking the arrow icon in the toolbar:

You can also use the dropdown to select a specific browser for debugging.

To debug with multiple browsers, select **Browse With**. In the **Browse With** dialog, hold down the CTRL key to select more than one browser. Click **Browse** to debug with the selected browsers. Browser Link also works if you launch a browser from outside Visual Studio and navigate to the application URL.

The Browser Link controls are located in the dropdown with the circular arrow icon. The arrow icon is the **Refresh** button.

To see which browsers are connected, hover the mouse over the **Refresh** button while debugging. The connected browsers are shown in a ToolTip window.

To refresh the connected browsers, click the **Refresh** button or press CTRL+ALT+ENTER. For example, the following screenshot shows an ASP.NET project, which I created using the MVC 5 project template. You can see the application running in two browsers at the top. At the bottom, the project is open in Visual Studio.

In Visual Studio, I changed the <h1> heading for the home page:

When I clicked the **Refresh** button, the change appeared in both browser windows:

Notes

- To enable Browser Link, set `debug=true` in the <compilation> element in the project's Web.config file.
- The application must be running on localhost.
- The application must target .NET 4.0 or later.

Viewing the Browser Link Dashboard

The Browser Link dashboard shows information about the Browser Link connections. To view the dashboard, select the Browser Link dropdown menu (the small arrow next to the **Refresh** button). Then click **Browser Link Dashboard**.

The dashboard lists the connected Browsers and the URL to which each browser has navigated.

The **Prerequisites** section shows any steps needed to enable Browser Link for that project. For example, the following screenshot shows a project where "debug" is set to false in the Web.config file.

Enabling Browser Link for Static HTML Files

To enable Browser Link for static HTML files, add the following to your Web.config file.

```
<configuration>
  <system.webServer>
    <handlers>
      <add name="Browser Link for HTML" path="*.html" verb="*"
           type="System.Web.StaticFileHandler, System.Web, Version=4.0.0.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a"
           resourceType="File" preCondition="integratedMode" />
    </handlers>
  </system.webServer>
</configuration>
```

For performance reasons, remove this setting when you publish your project.

Disabling Browser Link

Browser Link is enabled by default. There are several ways to disable it:

- In the Browser Link dropdown menu, uncheck **Enable Browser Link**.

- In the Web.config file, add a key named "vs:EnableBrowserLink" with the value "false" in the appSettings section.

```
<appSettings>
  <add key="vs:EnableBrowserLink" value="false"/>
</appSettings>
```

- In the Web.config file, set debug to false.

```
<system.web>
  <compilation debug="false" targetFramework="4.5" />
</system.web>
```

How Does It Work?

Browser Link uses SignalR to create a communication channel between Visual Studio and the browser. When Browser Link is enabled, Visual Studio acts as a SignalR server that multiple clients (browsers) can connect to. Browser Link also registers an HTTP module with ASP.NET. This module injects special <script> references into every page request from the server. You can see the script references by selecting "View source" in the browser.

```
83 <!-- Visual Studio Browser Link -->
84 <script type="application/json" id="__browserLink_initializationData">
85     {"appName":"InternetExplorer","requestId":"c762efb8f5fc495d8bf82460d3867b9d"}
86 </script>
87 <script type="text/javascript" src="http://localhost:57058/cb8085b94cca43e58d81a3e9580baf51/browserLin
88 <!-- End Browser Link -->
89
90 </body>
91 </html>
92
```

Your source files are not modified. The HTTP module injects the script references dynamically.

Because the browser-side code is all JavaScript, it works on all browsers that SignalR supports, without requiring

any browser plug-in.

ASP.NET and Web Tools for Visual Studio 2013 Release Notes

4/10/2020 • 33 minutes to read • Edit Online

by Microsoft

This document describes the release of ASP.NET and Web Tools for Visual Studio 2013.

Contents

- Installation Notes
- Documentation
- Software Requirements

New Features in ASP.NET and Web Tools for Visual Studio 2013

- One ASP.NET
- New Web Project Experience
- ASP.NET Scaffolding
- Browser Link
- Visual Studio Web Editor Enhancements
- Azure App Service Web Apps Support in Visual Studio
- Web Publish Enhancements
- NuGet 2.7
- ASP.NET Web Forms
- ASP.NET MVC 5
- ASP.NET Web API 2
- ASP.NET SignalR
- ASP.NET Identity
- Microsoft OWIN Components
- Entity Framework 6
- ASP.NET Razor 3
- ASP.NET App Suspend
- Known Issues and Breaking Changes

Installation Notes

ASP.NET and Web Tools for Visual Studio 2013 are bundled in the main installer and can be downloaded here.

Documentation

Tutorials and other information about ASP.NET and Web Tools for Visual Studio 2013 are available from the ASP.NET web site.

Software Requirements

ASP.NET and Web Tools requires Visual Studio 2013.

New Features in ASP.NET and Web Tools for Visual Studio 2013

The following sections describe the features that have been introduced in the release.

One ASP.NET

With the release of Visual Studio 2013, we have taken a step towards unifying the experience of using ASP.NET technologies, so that you can easily mix and match the ones you want. For example, you can start a project using MVC and easily add Web Forms pages to the project later, or scaffold Web APIs in a Web Forms project. One ASP.NET is all about making it easier for you as a developer to do the things you love in ASP.NET. No matter what technology you choose, you can have confidence that you are building on the trusted underlying framework of One ASP.NET.

New Web Project Experience

We have enhanced the experience of creating new web projects in Visual Studio 2013. In the **New ASP.NET Web Project** dialog you can select the project type you want, configure any combination of technologies (Web Forms, MVC, Web API), configure authentication options, and add a unit test project.

The new dialog enables you to change the default authentication options for many of the templates. For example, when you create an ASP.NET Web Forms project you can select any of the following options:

- No Authentication
- Individual User Accounts (ASP.NET membership or social provider log in)
- Organizational Accounts (Active Directory in an internet application)
- Windows Authentication (Active Directory in an intranet application)

For more information about the new process for creating web projects, see Creating ASP.NET Web Projects in Visual Studio 2013. For more information about the new authentication options, see ASP.NET Identity later in this document.

ASP.NET Scaffolding

ASP.NET Scaffolding is a code generation framework for ASP.NET Web applications. It makes it easy to add boilerplate code to your project that interacts with a data model.

In previous versions of Visual Studio, scaffolding was limited to ASP.NET MVC projects. With Visual Studio 2013, you can now use scaffolding for any ASP.NET project, including Web Forms. Visual Studio 2013 does not currently support generating pages for a Web Forms project, but you can still use scaffolding with Web Forms by adding MVC dependencies to the project. Support for generating pages for Web Forms will be added in a future update.

When using scaffolding, we ensure that all required dependencies are installed in the project. For example, if you start with an ASP.NET Web Forms project and then use scaffolding to add a Web API Controller, the required NuGet packages and references are added to your project automatically.

To add MVC scaffolding to a Web Forms project, add a **New Scaffolded Item** and select **MVC 5 Dependencies** in the dialog window. There are two options for scaffolding MVC; Minimal and Full. If you select Minimal, only the NuGet packages and references for ASP.NET MVC are added to your project. If you select the Full option, the Minimal dependencies are added, as well as the required content files for an MVC project.

Support for scaffolding async controllers uses the new async features from Entity Framework 6.

For more information and tutorials, see ASP.NET Scaffolding Overview.

Browser Link – SignalR channel between browser and Visual Studio

The new Browser Link feature lets you connect multiple browsers to Visual Studio and refresh them all by clicking a button in the toolbar. You can connect multiple browsers to your development site, including mobile emulators, and click refresh to refresh all the browsers all at the same time. Browser Link also exposes an API to enable developers to write Browser Link extensions.

By enabling developers to take advantage of the Browser Link API, it becomes possible to create very advanced

scenarios that crosses boundaries between Visual Studio and any browser that's connected. Web Essentials takes advantage of the API to create an integrated experience between Visual Studio and the browser's developer tools, remote controlling mobile emulators and a lot more.

Visual Studio Web Editor Enhancements

Visual Studio 2013 includes a new HTML editor for Razor files and HTML files in web applications. The new HTML editor provides a single unified schema based on HTML5. It has automatic brace completion, jQuery UI and AngularJS attribute IntelliSense, attribute IntelliSense Grouping, ID and class name Intellisense, and other improvements including better performance, formatting and SmartTags.

The following screenshot demonstrates using Bootstrap attribute IntelliSense in the HTML editor.

Visual Studio 2013 also comes with both CoffeeScript and LESS editors built in. The LESS editor comes with all the cool features from the CSS editor and has specific Intellisense for variables and mixins across all the LESS documents in the @import chain.

Azure App Service Web Apps Support in Visual Studio

In Visual Studio 2013 with the Azure SDK for .NET 2.2, you can use **Server Explorer** to interact directly with your remote web apps. You can sign in to your Azure account, create new web apps, configure apps, view real-time logs, and more. Coming soon after SDK 2.2 is released, you'll be able to run in debug mode remotely in Azure. Most of the new features for Azure App Service Web Apps also work in Visual Studio 2012 when you install the current release of the Azure SDK for .NET.

For more information, see the following resources:

- Create an ASP.NET web app in Azure App Service
- Troubleshoot a web app in Azure App Service using Visual Studio

Web Publish Enhancements

Visual Studio 2013 includes new and enhanced Web Publish features. Here are a few of them:

- Easily automate Web.config file encryption. (This link and the following two point to documentation on MSDN that might not be available until late in the day on 10/17.)
- Easily automate taking an application offline during deployment.
- Configure Web Deploy to use file checksum instead of last-changed date for determining which files should be copied to the server.
- Quickly publish individual selected files (including Web.config) when you're using the FTP or file system publish methods as well as with Web Deploy.

For more information about ASP.NET web deployment, see the ASP.NET site.

NuGet 2.7

NuGet 2.7 includes a rich set of new features which are described in detail at NuGet 2.7 Release Notes.

This version of NuGet also removes the need to provide explicit consent for NuGet's package restore feature to download packages. Consent (and the associated checkbox in NuGet's preferences dialog) is now granted by installing NuGet. Now package restore simply works by default.

ASP.NET Web Forms

One ASP.NET

The Web Forms project templates integrate seamlessly with the new One ASP.NET experience. You can add MVC and Web API support to your Web Forms project, and you can configure authentication using the One ASP.NET project creation wizard. For more information, see Creating ASP.NET Web Projects in Visual Studio 2013.

ASP.NET Identity

The Web Forms project templates support the new ASP.NET Identity framework. In addition, the templates now support creation of a Web Forms intranet project. For more information, see Authentication Methods in **Creating ASP.NET Web Projects in Visual Studio 2013**.

Bootstrap

The Web Forms templates use Bootstrap to provide a sleek and responsive look and feel that you can easily customize. For more information, see Bootstrap in the Visual Studio 2013 web project templates.

ASP.NET MVC 5

One ASP.NET

The Web MVC project templates integrate seamlessly with the new One ASP.NET experience. You can customize your MVC project and configure authentication using the One ASP.NET project creation wizard. An introductory tutorial to ASP.NET MVC 5 can be found at Getting Started with ASP.NET MVC 5.

For information on upgrading MVC 4 projects to MVC 5, see How to Upgrade an ASP.NET MVC 4 and Web API Project to ASP.NET MVC 5 and Web API 2.

ASP.NET Identity

The MVC project templates have been updated to use ASP.NET Identity for authentication and identity management. A tutorial featuring Facebook and Google authentication and the new membership API can be found at Create an ASP.NET MVC 5 App with Facebook and Google OAuth2 and OpenID Sign-on and Create an ASP.NET MVC app with auth and SQL DB and deploy to Azure App Service.

Bootstrap

The MVC project template has been updated to use Bootstrap to provide a sleek and responsive look and feel that you can easily customize. For more information, see Bootstrap in the Visual Studio 2013 web project templates.

Authentication filters

Authentication filters are a new kind of filter in ASP.NET MVC that run prior to authorization filters in the ASP.NET MVC pipeline and allow you to specify authentication logic per-action, per-controller, or globally for all controllers. Authentication filters process credentials in the request and provide a corresponding principal. Authentication filters can also add authentication challenges in response to unauthorized requests.

Filter overrides

You can now override which filters apply to a given action method or controller by specifying an override filter.

Override filters specify a set of filter types that should not be run for a given scope (action or controller). This allows you to configure filters that apply globally but then exclude certain global filters from applying to specific actions or controllers.

Attribute routing

ASP.NET MVC now supports attribute routing, thanks to a contribution by Tim McCall, the author of http://attributerouting.net. With attribute routing you can specify your routes by annotating your actions and controllers.

ASP.NET Web API 2

Attribute routing

ASP.NET Web API now supports attribute routing, thanks to a contribution by Tim McCall, the author of http://attributerouting.net. With attribute routing you can specify your Web API routes by annotating your actions and controllers like this:

```
[RoutePrefix("orders")]
public class OrdersController : ApiController
{
    [Route("{id}")]
    public Order Get(int id) { }
    [Route("{id}/approve")]
    public Order Approve(int id) { }
}
```

Attribute routing gives you more control over the URIs in your web API. For example, you can easily define a resource hierarchy using a single API controller:

```
public class MoviesController : ApiController
{
    [Route("movies")]
    public IEnumerable<Movie> Get() { }
    [Route("actors/{actorId}/movies")]
    public IEnumerable<Movie> GetByActor(int actorId) { }
    [Route("directors/{directorId}/movies")]
    public IEnumerable<Movie> GetByDirector(int directorId) { }
}
```

Attribute routing also provides a convenient syntax for specifying optional parameters, default values, and route constraints:

```
// Optional parameter
[Route("people/{name?}")]
// Default value
[Route("people/{name=Dan}")]
// Constraint: Alphabetic characters only.
[Route("people/{name:alpha}")]
```

For more information about attribute routing, see Attribute Routing in Web API 2.

OAuth 2.0

The Web API and Single Page Application project templates now support authorization using OAuth 2.0. OAuth 2.0 is a framework for authorizing client access to protected resources. It works for a variety of clients including browsers and mobile devices.

Support for OAuth 2.0 is based on new security middleware provided by the Microsoft OWIN Components for

bearer authentication and implementing the authorization server role. Alternatively, clients can be authorized using an organizational authorization server, such as Azure Active Directory or ADFS in Windows Server 2012 R2.

OData Improvements

Support for $select, $expand, $batch, and $value

ASP.NET Web API OData now has full support for $select, $expand, and $value. You can also use $batch for request batching and processing of change sets.

The $select and $expand options let you change the shape of the data that is returned from an OData endpoint. For more information, see Introducing $select and $expand support in Web API OData.

Improved extensibility

The OData formatters are now extensible. You can add Atom entry metadata, support named stream and media link entries, add instance annotations, and customize how links are generated.

Type-less support

You can now build OData services without needing to define CLR types for your entity types. Instead, your OData controllers can take or return instances of **IEdmObject**, which are the OData formatters serialize/deserialize.

Reuse an existing model

If you already have an existing entity data model (EDM), you can now reuse it directly, instead of having to build a new one. For example, if you are using Entity Framework, you can use the EDM that EF builds for you.

Request Batching

Request batching combines multiple operations into a single HTTP POST request, to reduce network traffic and provide a smoother, less chatty user interface. ASP.NET Web API now supports several strategies for request batching:

- Use the $batch endpoint of an OData service.
- Package multiple requests into a single MIME multipart request.
- Use a custom batching format.

To enable request batching, simply add a route with a batching handler to your Web API configuration:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Routes.MapHttpBatchRoute(
            routeName: "WebApiBatch",
            routeTemplate: "api/batch",
            batchHandler: new DefaultHttpBatchHandler(GlobalConfiguration.DefaultServer));
    }
}
```

You can also control whether requests or executed sequentially or in any order.

Portable ASP.NET Web API Client

You can now use the ASP.NET Web API Client to create portable class libraries that work across your Windows Store and Windows Phone 8 applications. You can also create portable formatters that can be shared across client and server.

Improved Testability

Web API 2 makes it much easier to unit test your API controllers. Just instantiate your API controller with your request message and configuration, and then call the action method you wish to test. It is also easy to mock the

UrlHelper class, for action methods that perform link generation.

IHttpActionResult

You can now implement IHttpActionResult to encapsulate the result of your Web API action methods. An IHttpActionResult returned from a Web API action method is executed by the ASP.NET Web API runtime to produce the resultant response message. An IHttpActionResult can be returned from any Web API action to simplify unit testing of your Web API implementation. For convenience a number of IHttpActionResult implementations are provided out of the box including results for returning specific status codes, formatted content or content-negotiated responses.

HttpRequestContext

The new **HttpRequestContext** tracks any state that is tied to the request but is not immediately available from the request. For example, you can use the **HttpRequestContext** to get route data, the principal associated with the request, the client certificate, the **UrlHelper** and the virtual path root. You can easily create an **HttpRequestContext** for unit testing purposes.

Because the principal for the request is flowed with the request instead of relying on **Thread.CurrentPrincipal**, the principal is now available throughout the lifetime of the request while it is in the Web API pipeline.

CORS

Thanks to another great contribution from Brock Allen, ASP.NET now fully supports Cross Origin Request Sharing (CORS).

Browser security prevents a web page from making AJAX requests to another domain. CORS is a W3C standard that allows a server to relax the same-origin policy. Using CORS, a server can explicitly allow some cross-origin requests while rejecting others.

Web API 2 now supports CORS, including automatic handling of preflight requests. For more information, see Enabling Cross-Origin Requests in ASP.NET Web API.

Authentication Filters

Authentication filters are a new kind of filter in ASP.NET Web API that run prior to authorization filters in the ASP.NET Web API pipeline and allow you to specify authentication logic per-action, per-controller, or globally for all controllers. Authentication filters process credentials in the request and provide a corresponding principal. Authentication filters can also add authentication challenges in response to unauthorized requests.

Filter Overrides

You can now override which filters apply to a given action method or controller, by specifying an override filter. Override filters specify a set of filter types that should not run for a given scope (action or controller). This allows you to add global filters, but then exclude some from specific actions or controllers.

OWIN Integration

ASP.NET Web API now fully supports OWIN and can be run on any OWIN capable host. Also included is a **HostAuthenticationFilter** that provides integration with the OWIN authentication system.

With OWIN integration, you can self-host Web API in your own process alongside other OWIN middleware, such as SignalR. For more information, see Use OWIN to Self-Host ASP.NET Web API.

ASP.NET SignalR 2.0

The following sections describe features of SignalR 2.0.

- Built on OWIN
- MapHubs and MapConnection are now MapSignalR
- Cross-Domain Support

- iOS and Android support via MonoTouch and MonoDroid
- Portable .NET Client
- New Self-Host Package
- Backward-compatible server support
- Removed server support for .NET 4.0
- Sending a message to a list of clients and groups
- Sending a message to a specific user
- Better error handling support
- Easier unit testing of hubs
- JavaScript error handling

For an example of how to upgrade an existing 1.x project to SignalR 2.0, see Upgrading a SignalR 1.x Project.

Built on OWIN

SignalR 2.0 is built completely on OWIN (the Open Web Interface for .NET). This change makes the setup process for SignalR much more consistent between web-hosted and self-hosted SignalR applications, but has also required a number of API changes.

MapHubs and MapConnection are now MapSignalR

For compatibility with OWIN standards, these methods have been renamed to `MapSignalR`. `MapSignalR` called without parameters will map all hubs (as `MapHubs` does in version 1.x); to map individual **PersistentConnection** objects, specify the connection type as the type parameter, and the URL extension for the connection as the first argument.

The `MapSignalR` method is called in an Owin startup class. Visual Studio 2013 contains a new template for an Owin startup class; to use this template, do the following:

1. Right-click on the project
2. Select **Add**, **New Item...**
3. Select **Owin Startup class**. Name the new class **Startup.cs**.

In a **Web application,** the Owin startup class containing the `MapSignalR` method is then added to Owin's startup process using an entry in the application settings node of the Web.Config file, as shown below.

In a **Self-hosted application**, the Startup class is passed as the type parameter of the `WebApp.Start` method.

Mapping hubs and connections in SignalR 1.x (from the global application file in a web application):

```
protected void Application_Start(object sender, EventArgs e)
{
    // Map all hubs to "/signalr"
    RouteTable.Routes.MapHubs();
    // Map the Echo PersistentConnection to "/echo"
    RouteTable.Routes.MapConnection<myconnection>("echo", "/echo");
}
```

Mapping hubs and connections in SignalR 2.0 (from an Owin Startup class file):

```
using Microsoft.AspNet.SignalR;
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(MyWebApplication.Startup))]

namespace MyWebApplication
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Map all hubs to "/signalr"
            app.MapSignalR();
            // Map the Echo PersistentConnection to "/echo"
            app.MapSignalR<echoconnection>("/echo");
        }
    }
}
```

In a **Self-hosted application**, the Startup class is passed as the type parameter for the `WebApp.Start` method, as shown below.

```
string url = "http://localhost:8080";
using (WebApp.Start<startup>(url))
{
    Console.WriteLine("Server running on {0}", url);
    Console.ReadLine();
}
```

Cross-Domain Support

In SignalR 1.x, cross domain requests were controlled by a single EnableCrossDomain flag. This flag controlled both JSONP and CORS requests. For greater flexibility, all CORS support has been removed from the server component of SignalR (JavaScript clients still use CORS normally if it is detected that the browser supports it), and new OWIN middleware has been made available to support these scenarios.

In SignalR 2.0, If JSONP is required on the client (to support cross-domain requests in older browsers), it will need to be enabled explicitly by setting `EnableJSONP` on the `HubConfiguration` object to `true`, as shown below. JSONP is disabled by default, as it is less secure than CORS.

To add the new CORS middleware in SignalR 2.0, add the `Microsoft.Owin.Cors` library to your project, and call `UseCors` before your SignalR middleware, as shown in the section below.

Adding Microsoft.Owin.Cors to your project: To install this library, run the following command in the Package Manager Console:

```
Install-Package Microsoft.Owin.Cors
```

This command will add the 2.0.0 version of the package to your project.

Calling UseCors

The following code snippets demonstrate how to implement cross-domain connections in SignalR 1.x and 2.0.

Implementing cross-domain requests in SignalR 1.x (from the global application file)

```
protected void Application_Start(object sender, EventArgs e)
{
    var hubConfiguration = new HubConfiguration();
    hubConfiguration.EnableCrossDomain = true;
    RouteTable.Routes.MapHubs(hubConfiguration);
}
```

Implementing cross-domain requests in SignalR 2.0 (from a C# code file)

The following code demonstrates how to enable CORS or JSONP in a SignalR 2.0 project. This code sample uses `Map` and `RunSignalR` instead of `MapSignalR`, so that the CORS middleware runs only for the SignalR requests that require CORS support (rather than for all traffic at the path specified in `MapSignalR`.) `Map` can also be used for any other middleware that needs to run for a specific URL prefix, rather than for the entire application.

```
using Microsoft.AspNet.SignalR;
using Microsoft.Owin.Cors;
using Owin;

[assembly: OwinStartup(typeof(MyWebApplication.Startup))]

namespace MyWebApplication
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Branch the pipeline here for requests that start with "/signalr"
            app.Map("/signalr", map =>
            {
                // Setup the CORS middleware to run before SignalR.
                // By default this will allow all origins. You can
                // configure the set of origins and/or http verbs by
                // providing a cors options with a different policy.
                map.UseCors(CorsOptions.AllowAll);
                var hubConfiguration = new HubConfiguration
                {
                    // You can enable JSONP by uncommenting line below.
                    // JSONP requests are insecure but some older browsers (and some
                    // versions of IE) require JSONP to work cross domain
                    // EnableJSONP = true
                };
                // Run the SignalR pipeline. We're not using MapSignalR
                // since this branch already runs under the "/signalr"
                // path.
                map.RunSignalR(hubConfiguration);
            });
        }
    }
}
```

iOS and Android support via MonoTouch and MonoDroid

Support has been added for iOS and Android clients using MonoTouch and MonoDroid components from the Xamarin library. For more information on how to use them, see Using Xamarin Components. These components will be available in the Xamarin Store when the SignalR RTW release is available.

Portable .NET client

To better facilitate cross-platform development, the Silverlight, WinRT and Windows Phone clients have been replaced with a single portable .NET client that supports the following platforms:

- NET 4.5

- Silverlight 5
- WinRT (.NET for Windows Store Apps)
- Windows Phone 8

New Self-Host Package

There is now a NuGet package to make it easier to get started with SignalR Self-Host (SignalR applications that are hosted in a process or other application, rather than being hosted in a web server). To upgrade a self-host project built with SignalR 1.x, remove the Microsoft.AspNet.SignalR.Owin package, and add the Microsoft.AspNet.SignalR.SelfHost package. For more information on getting started with the self-host package, see Tutorial: SignalR Self-Host.

Backward-compatible server support

In previous versions of SignalR, the versions of the SignalR package used in the client and the server needed to be identical. In order to support thick-client applications that would be difficult to update, SignalR 2.0 now supports using a newer server version with an older client. **Note: SignalR 2.0 does not support servers built with older versions with newer clients.**

Removed server support for .NET 4.0

SignalR 2.0 has dropped support for server interoperability with .NET 4.0. .NET 4.5 must be used with SignalR 2.0 servers. There is still a .NET 4.0 client for SignalR 2.0.

Sending a message to a list of clients and groups

In SignalR 2.0, it's possible to send a message using a list of client and group IDs. The following code snippets demonstrate how to do this.

Sending a message to a list of clients and groups using PersistentConnection

```
using Microsoft.AspNet.SignalR;
using System.Collections.Generic;
public class ChatConnection : PersistentConnection
{
    static List<string> ConnectionIds = new List<string>();
    static List<string> groups = new List<string>{"chatGroup", "chatGroup2"};
    protected override System.Threading.Tasks.Task OnReceived(IRequest request, string connectionId, string
data)
    {
        Connection.Send(ConnectionIds, data);
        Groups.Send(groups, data);
        return base.OnReceived(request, connectionId, data);
    }
    protected override System.Threading.Tasks.Task OnConnected(IRequest request, string connectionId)
    {
        ConnectionIds.Add(connectionId);
        Groups.Add(connectionId, "chatGroup");
        return base.OnConnected(request, connectionId);
    }
    protected override System.Threading.Tasks.Task OnDisconnected(IRequest request, string connectionId)
    {
        ConnectionIds.Remove(connectionId);
        return base.OnDisconnected(request, connectionId);
    }
}
```

Sending a message to a list of clients and groups using Hubs

```
using Microsoft.AspNet.SignalR;
using System.Collections.Generic;
public class ChatHub : Hub
{
    static List<string> ConnectionIds = new List<string>();
    static List<string> groups = new List<string> { "chatGroup", "chatGroup2" };
    public void Send(string name, string message)
    {
        // Call the broadcastMessage method to update clients.
        Clients.Clients(ConnectionIds).broadcastMessage(name, message);
        Clients.Groups(groups).broadcastMessage(name, message);
    }
    public override System.Threading.Tasks.Task OnConnected()
    {
        ConnectionIds.Add(Context.ConnectionId);
        Groups.Add(Context.ConnectionId, "chatGroup");
        return base.OnConnected();
    }
    public override System.Threading.Tasks.Task OnDisconnected()
    {
        ConnectionIds.Remove(Context.ConnectionId);
        return base.OnDisconnected();
    }
}
```

Sending a message to a specific user

This feature allows users to specify what the userId is based on an IRequest via a new interface IUserIdProvider:

The IUserIdProvider interface

```
public interface IUserIdProvider
{
    string GetUserId(IRequest request);
}
```

By default there will be an implementation that uses the user's IPrincipal.Identity.Name as the user name.

In hubs, you'll be able to send messages to these users via a new API:

Using the Clients.User API

```
public class MyHub : Hub
{
    public void Send(string userId, string message)
    {
        Clients.User(userId).send(message);
    }
}
```

Better Error Handling Support

Users can now throw **HubException** from any hub invocation. The constructor of the **HubException** can take a string message and an object extra error data. SignalR will auto-serialize the exception and send it to the client where it will be used to reject/fail the hub method invocation.

The **show detailed hub exceptions** setting has no bearing on **HubException** being sent back to the client or not; it is always sent.

Server-side code demonstrating sending a HubException to the client

```
public class MyHub : Hub
{
    public void Send(string message)
    {
        if(message.Contains("<script>"))
        {
            throw new HubException("This message will flow to the client", new { user =
Context.User.Identity.Name, message = message });
        }

        Clients.All.send(message);
    }
}
```

JavaScript client code demonstrating responding to a HubException sent from the server

```
myHub.server.send("<script>")
            .fail(function (e) {
                if (e.source === 'HubException') {
                    console.log(e.message + ' : ' + e.data.user);
                }
            });
```

.NET client code demonstrating responding to a HubException sent from the server

```
try
{
    await myHub.Invoke("Send", "<script>");
}
catch(HubException ex)
{
    Conosle.WriteLine(ex.Message);
}
```

Easier unit testing of hubs

SignalR 2.0 includes an interface called `IHubCallerConnectionContext` on Hubs that makes it easier to create mock client side invocations. The following code snippets demonstrate using this interface with popular test harnesses xUnit.net and moq.

Unit testing SignalR with xUnit.net

```
[Fact]
public void HubsAreMockableViaDynamic()
{
    bool sendCalled = false;
    var hub = new MyHub();
    var mockClients = new Mock<IHubCallerConnectionContext>();
    hub.Clients = mockClients.Object;
    dynamic all = new ExpandoObject();
    all.send = new Action<string>(message =>
    {
        sendCalled = true;
    });
    mockClients.Setup(m => m.All).Returns((ExpandoObject)all);
    hub.Send("foo");
    Assert.True(sendCalled);
}
```

Unit testing SignalR with moq

```
[Fact]
public interface IClientContract
{
    void send(string message);
}
public void HubsAreMockableViaType()
{
    var hub = new MyHub();
    var mockClients = new Mock<IHubCallerConnectionContext>();
    var all = new Mock<IClientContract>();
    hub.Clients = mockClients.Object;
    all.Setup(m => m.send(It.IsAny<string>())).Verifiable();
    mockClients.Setup(m => m.All).Returns(all.Object);
    hub.Send("foo");
    all.VerifyAll();
```

JavaScript error handling

In SignalR 2.0, all JavaScript error handling callbacks return JavaScript error objects instead of raw strings. This allows SignalR to flow richer information to your error handlers. You can get the inner exception from the `source` property of the error.

JavaScript client code that handles the Start.Fail exception

```
connection.start().fail(function(e) {
    console.log('The error is: ' + e.message);
});
```

ASP.NET Identity

New ASP.NET Membership System

ASP.NET Identity is the new membership system for ASP.NET applications. ASP.NET Identity makes it easy to integrate user-specific profile data with application data. ASP.NET Identity also allows you to choose the persistence model for user profiles in your application. You can store the data in a SQL Server database or another data store, including NoSQL data stores such as Azure Storage Tables. For more information, see Individual User Accounts in **Creating ASP.NET Web Projects in Visual Studio 2013**.

Claims-based authentication

ASP.NET now supports claims-based authentication, where the user's identity is represented as a set of claims from a trusted issuer. Users can be authenticated using a username and password maintained in an application database, or using social identity providers (for example: Microsoft Accounts, Facebook, Google, Twitter), or using organizational accounts through Azure Active Directory or Active Directory Federation Services (ADFS).

Integration with Azure Active Directory and Windows Server Active Directory

You can now create ASP.NET projects that use Azure Active Directory or Windows Server Active Directory (AD) for authentication. For more information, see Organizational Accounts in **Creating ASP.NET Web Projects in Visual Studio 2013**.

OWIN Integration

ASP.NET authentication is now based on OWIN middleware that can be used on any OWIN-based host. For more information about OWIN, see the following Microsoft OWIN Components section.

Microsoft OWIN Components

Open Web Interface for .NET (OWIN) defines an abstraction between .NET web servers and web applications. OWIN decouples the web application from the server, making web applications host-agnostic. For example, you

can host an OWIN-based web application in IIS or self-host it in a custom process.

Changes introduced in the Microsoft OWIN components (also known as the Katana project) include new server and host components, new helper libraries and middleware, and new authentication middleware.

For more information about OWIN and Katana, see What's new in OWIN and Katana.

Note: OWIN applications cannot run in IIS classic mode; they must be run in integrated mode.

Note: OWIN applications must be run in full trust.

New Servers and Hosts

With this release, new components were added to enable self-host scenarios. These components include the following NuGet packages:

- **Microsoft.Owin.Host.HttpListener**. Provides an OWIN server that uses **HttpListener** to listen for HTTP requests and direct them into the OWIN pipeline.
- **Microsoft.Owin.Hosting** Provides a library for developers who wish to self-host an OWIN pipeline in a custom process, such as a console application or Windows service.
- **OwinHost**. Provides a stand-alone executable that wraps `Microsoft.Owin.Hosting` and lets you self-host an OWIN pipeline without having to write a custom host application.

In addition, the `Microsoft.Owin.Host.SystemWeb` package now enables middleware to provide hints to the **SystemWeb** server, indicating that the middleware should be called during a specific ASP.NET pipeline stage. This feature is particularly useful for authentication middleware, which should run early in the ASP.NET pipeline.

Helper Libraries and Middleware

Although you can write OWIN components using only the function and type definitions from the OWIN specification, the new `Microsoft.Owin` package provides a more user-friendly set of abstractions. This package combines several earlier packages (e.g., `Owin.Extensions`, `Owin.Types`) into a single, well-structured object model that can then be easily used by other OWIN components. In fact, the majority of Microsoft OWIN components now use this package.

> **NOTE**
> OWIN applications cannot run in IIS classic mode; they must be run in integrated mode.

> **NOTE**
> OWIN applications must be run in full trust.

This release also includes the Microsoft.Owin.Diagnostics package, which includes middleware to validate a running OWIN application, plus error-page middleware to help investigate failures.

Authentication Components

The following authentication components are available.

- **Microsoft.Owin.Security.ActiveDirectory**. Enables authentication using on-premise or cloud-based directory services.
- **Microsoft.Owin.Security.Cookies** Enables authentication using cookies. This package was previously named `Microsoft.Owin.Security.Forms`.
- **Microsoft.Owin.Security.Facebook** Enables authentication using Facebook's OAuth-based service.
- **Microsoft.Owin.Security.Google** Enables authentication using Google's OpenID-based service.
- **Microsoft.Owin.Security.Jwt** Enables authentication using JWT tokens.

- **Microsoft.Owin.Security.MicrosoftAccount** Enables authentication using Microsoft accounts.
- **Microsoft.Owin.Security.OAuth**. Provides an OAuth authorization server as well as middleware for authenticating bearer tokens.
- **Microsoft.Owin.Security.Twitter** Enables authentication using Twitter's OAuth-based service.

This release also includes the `Microsoft.Owin.Cors` package, which contains middleware for processing cross-origin HTTP requests.

> **NOTE**
> Support for JWT signing has been removed in the final version of Visual Studio 2013.

Entity Framework 6

For a list of new features and other changes in Entity Framework 6, see Entity Framework Version History.

ASP.NET Razor 3

ASP.NET Razor 3 includes the following new features:

- Support for Tab editing. Previously, the **Format Document** command, auto indenting, and auto formatting in Visual Studio did not work correctly when using the **Keep Tabs** option. This change corrects Visual Studio formatting for Razor code for tab formatting.
- Support for URL Rewrite rules when generating links.
- Removal of security transparent attribute.

  > **NOTE**
  > This is a breaking change, and makes Razor 3 incompatible with MVC4 and earlier, while Razor 2 is incompatible with MVC5 or assemblies compiled against MVC5.

Razor 3 issues fixed in Visual Studio 2013 from pre-release versions can be found here.

ASP.NET App Suspend

ASP.NET App Suspend is a game-changing feature in the .NET Framework 4.5.1 that radically changes the user experience and economic model for hosting large numbers of ASP.NET sites on a single machine. For more information, see ASP.NET App Suspend – responsive shared .NET web hosting.

Known Issues and Breaking Changes

This section describes known issues and breaking changes in the ASP.NET and Web Tools for Visual Studio 2013.

NuGet

- New package restore doesn't work on Mono when using SLN file – will be fixed in an upcoming nuget.exe download and NuGet.CommandLine package update.
- New package restore doesn't work with Wix projects – will be fixed in an upcoming nuget.exe download and NuGet.CommandLine package update.
- Automatic Package restore doesn't work for projects under a solution folder – will be fixed in NuGet 2.8.

ASP.NET Web API

1. `ODataQueryOptions<T>.ApplyTo(IQueryable)` doesn't return `IQueryable<T>` always, as we added support for `$select` and `$expand`.

Our earlier samples for `ODataQueryOptions<T>` always casted the return value from `ApplyTo` to `IQueryable<T>`. This worked earlier because the query options that we supported earlier (`$filter`, `$orderby`, `$skip`, `$top`) do not change the shape of the query. Now that we support `$select` and `$expand` the return value from `ApplyTo` will not be `IQueryable<T>` always.

```
// Sample ODataQueryOptions<T> usage from earlier
public IQueryable<Customer> Get(ODataQueryOptions<Customer> query)
{
    IQueryable<customer> result="query.ApplyTo(_customers)" as iqueryable<customer>; return result;
}
```

If you are using the sample code from earlier, it will continue working if the client does not send `$select` and `$expand`. However, if you wish to support `$select` and `$expand` you have to change that code to this.

```
public IHttpActionResult Get(ODataQueryOptions<Customer> query)
{
    IQueryable result = query.ApplyTo(_customers);
    return Ok(result, result.GetType());
}

private IHttpActionResult Ok(object content, Type type)
{
    Type resultType = typeof(OkNegotiatedContentResult<>).MakeGenericType(type);
    return Activator.CreateInstance(resultType, content, this) as IHttpActionResult;
}
```

2. **Request.Url or RequestContext.Url is null during a batch request**

   In a batching scenario, **UrlHelper** is null when accessed from **Request.Url** or **RequestContext.Url**.

   This issue is currently tracked here: BatchRequestContext.Url is null for batching request.

   The workaround for this issue is to create a new instance of **UrlHelper**, as in the following example:

   Creating a new instance of UrlHelper

```
if (RequestContext.Url == null)
{
    RequestContext.Url = new UrlHelper(Request);
}
```

ASP.NET MVC

1. When using MVC5 and OrgAuth, if you have views which do AntiForgerToken validation, you might come across the following error when you post data to the view:

   Error:

   Server Error in '/' Application.

   A claim of type 'http://schemas.xmlsoap.org/ws/2005/05/identity/claims/nameidentifier' or 'https://schemas.microsoft.com/accesscontrolservice/2010/07/claims/identityprovider' was not present on the provided ClaimsIdentity. To enable anti-forgery token support with claims-based authentication, please verify that the configured claims provider is providing both of these claims on the ClaimsIdentity instances it generates. If the configured claims provider instead uses a different claim type as a unique identifier, it can be configured by setting the static property AntiForgeryConfig.UniqueClaimTypeIdentifier.

   Workaround:

Add the following line in Global.asax to fix it:

```
AntiForgeryConfig.UniqueClaimTypeIdentifier = ClaimTypes.Name;
```

This will be fixed for the next release.

2. After upgrading an MVC4 app to MVC5, build the solution and launch it. You should see the following error:

   [A]System.Web.WebPages.Razor.Configuration.HostSection cannot be cast to [B]System.Web.WebPages.Razor.Configuration.HostSection. Type A originates from 'System.Web.WebPages.Razor, Version=2.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35' in the context 'Default' at location 'C:\windows\Microsoft.Net\assembly\GAC_MSIL\System.Web.WebPages.Razor\v4.0_2.0.0.0__31bf3856ad364e35\System.Web.WebPages.Razor.dll'. Type B originates from 'System.Web.WebPages.Razor, Version=3.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35' in the context 'Default' at location 'C:\Windows\Microsoft.NET\Framework\v4.0.30319\Temporary ASP.NET Files\root\6d05bbd0\e8b5908e\assembly\dl3\c9cbca63\f8910382_6273ce01\System.Web.WebPages.Razor.dll'.

   To fix the above error, open *all* the Web.config files (including the ones in the Views folder) in your project and do the following:

   a. Update all occurrences of version "4.0.0.0" of "System.Web.Mvc" to "5.0.0.0".

   b. Update all occurrences of version "2.0.0.0" of "System.Web.Helpers", "System.Web.WebPages" and "System.Web.WebPages.Razor" to "3.0.0.0"

      For example, after you make the above changes, the assembly bindings should look like this:

```
<dependentAssembly>
  <assemblyIdentity name="System.Web.Helpers" publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-2.0.0.0" newVersion="3.0.0.0" />
  </dependentAssembly>
  <dependentAssembly>
  <assemblyIdentity name="System.Web.WebPages" publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-2.0.0.0" newVersion="3.0.0.0" />
  </dependentAssembly>
  <dependentAssembly>
  <assemblyIdentity name="System.Web.WebPages.Razor" publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-3.0.0.0" newVersion="3.0.0.0" />
  </dependentAssembly>
  <dependentAssembly>
  <assemblyIdentity name="System.Web.Mvc" publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-4.0.0.0" newVersion="5.0.0.0" />
</dependentAssembly>
```

      For information on upgrading MVC 4 projects to MVC 5, see How to Upgrade an ASP.NET MVC 4 and Web API Project to ASP.NET MVC 5 and Web API 2.

3. When using client-side validation with jQuery Unobtrusive Validation, the validation message is sometimes incorrect for an HTML input element with type='number'. The validation error for a required value ("The Age field is required") is shown when an invalid number is entered instead of the correct message that a valid number is required.

   This issue is commonly found with scaffolded code for a model with an integer property on the Create and Edit views.

   To work around this issue, change the editor helper from:

```
@Html.EditorFor(person => person.Age)
```

To:

```
@Html.TextBoxFor(person => person.Age)
```

4. ASP.NET MVC 5 no longer supports partial trust. Projects linking to the MVC or WebAPI binaries should remove the SecurityTransparent attribute and the AllowPartiallyTrustedCallers attribute. Removing these attributes will eliminate compiler errors such as the following.

```
Attempt by security transparent method ‘MyComponent' to access security critical type
'System.Web.Mvc.MvcHtmlString' failed. Assembly 'PagedList.Mvc, Version=4.3.0.0, Culture=neutral,
PublicKeyToken=abbb863e9397c5e1' is marked with the AllowPartiallyTrustedCallersAttribute, and uses the
level 2 security transparency model. Level 2 transparency causes all methods in
AllowPartiallyTrustedCallers assemblies to become security transparent by default, which may be the
cause of this exception.
```

> Note, as a side effect of this you cannot use 4.0 and 5.0 assemblies in the same application. You need to update all of them to 5.0.

SPA Template with Facebook authorization may cause instability in IE while the web site is hosted in intranet zone

The SPA template provides external log in with Facebook. When the project created with the template is running locally, signing in may cause IE to crash.

Solution:

1. Host the web site in internet zone; or
2. Test the scenario in a browser other than IE.

Web Forms Scaffolding

Web Forms Scaffolding has been removed from VS2013 and will be available in a future update to Visual Studio. However, you can still use scaffolding within a Web Forms project by adding MVC dependencies and generating scaffolding for MVC. Your project will contain a combination of Web Forms and MVC.

To add MVC to your Web Forms project, add a new scaffolded item and select **MVC 5 Dependencies**. Select either Minimal or Full depending on whether you need all of the content files, such as scripts. Then, add a scaffolded item for MVC, which will create views and a controller in your project.

MVC and Web API Scaffolding - HTTP 404, Not Found error

If an error is encountered when adding a scaffolded item to a project, it is possible your project will be left in an inconsistent state. Some of the changes made be scaffolding will be rolled back but other changes, such as the installed NuGet packages, will not be rolled back. If the routing configuration changes are rolled back, users will receive an HTTP 404 error when navigating to scaffolded items.

Workaround:

- To fix this error for MVC, add a new scaffolded item and select MVC 5 Dependencies (either Minimal or Full). This process will add all of the required changes to your project.
- To fix this error for Web API:
  1. Add the WebApiConfig class to your project.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.MapHttpAttributeRoutes();
        config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );
    }
}
```

```
Public Module WebApiConfig
    Public Sub Register(ByVal config As HttpConfiguration)
        config.MapHttpAttributeRoutes()
        config.Routes.MapHttpRoute(
          name:="DefaultApi",
          routeTemplate:="api/{controller}/{id}",
          defaults:=New With {.id = RouteParameter.Optional}
        )
    End Sub
End Module
```

2. Configure WebApiConfig.Register in the Application_Start method in Global.asax as follows:

```
public class WebApiApplication : System.Web.HttpApplication
{
    protected void Application_Start()
    {
        GlobalConfiguration.Configure(WebApiConfig.Register);
    }
}
```

```
Public Class WebApiApplication
     Inherits System.Web.HttpApplication

     Sub Application_Start()
       GlobalConfiguration.Configure(AddressOf WebApiConfig.Register)
     End Sub
End Class
```

ASP.NET and Web Tools 2013.2 for Visual Studio 2013 Release Notes

4/10/2020 • 14 minutes to read • Edit Online

by Microsoft

Installation Notes

ASP.NET and Web Tools for Visual Studio 2013.2 are bundled in the main installer and can be downloaded as part of Visual Studio 2013 Update 2.

Documentation

Tutorials and other information about ASP.NET and Web Tools for Visual Studio 2013.2 are available from the ASP.NET web site.

Software Requirements

ASP.NET and Web Tools for Visual Studio 2013.2 requires Visual Studio 2013.

New Features in ASP.NET and Web Tools for Visual Studio 2013.2

The following sections describe the features that have been introduced in the release.

- One ASP.NET Project Templates
- Support SSL when launching Web Applications on IIS Express
- Visual Studio Web Editor Enhancements
- Browser Link
- Support for Azure App Service Web Apps in Visual Studio
- Create remote Azure resources when creating a new Web project
- Web Publish Enhancements
- ASP.NET Scaffolding
- NuGet 2.8.1
- ASP.NET Web Forms
- ASP.NET MVC 5.1.2
- ASP.NET Web API 2.1.2
- ASP.NET Web Pages 3.1.2
- Entity Framework 6.1
- ASP.NET Identity 2.0.0
- Microsoft OWIN components
- ASP.NET SignalR 2.0.2

One ASP.NET Project Templates

- Updates to ASP.NET Project templates to support Account confirmation and Password Reset.
- Update ASP.NET Web API template to support authentication using On Premises Organizational Accounts.
- The ASP.NET SPA template now contains authentication that is based on MVC and server side views. The template has a WebAPI controller which can only be accessed by authenticated users.

Support SSL when launching Web Applications on IIS Express

To eliminate the security warning when browsing and debugging HTTPS on localhost, we added a dialog to allow Internet Explorer and Chrome to trust the self-signed IIS express SSL certificate.

For example, a web project property can be set to use SSL. Click F4 to bring up the properties dialog. Change **SSL Enabled** to true. Copy the SSL URL.

Set the web project property page web tab to use the HTTPS based URL (The SSL URL will be `https://localhost:44300/` unless you've previously created SSL Web Sites.)

Press CTRL+F5 to run the application. Follow the instructions to trust the self-signed certificate that IIS Express has generated.

Read the **Security Warning** dialog and then click **Yes** if you want to install the certificate representing localhost.

The site will be shown in IE or Chrome without the certificate warning in the browser.

Firefox uses its own certificate store, so it will display a warning.

Visual Studio Web Editor Enhancements

- **New JSON project item and editor**: We have added a JSON project item and editor to Visual Studio. Current JSON editor features include colorization, syntax validation, brace completion, outlining, tools option setting and more.

```
{"web-app": {
  "servlet": [
    {
      "servlet-name": "cofaxCDS",
      "servlet-class": "org.cofax.cds.CDSServlet",

        "dataLog": 1,
        "dataLogLocation": "/usr/local/tomcat/logs/dataLog.log",
        "dataLogMaxSize": "",
        "removePageCache": "/content/admin/remove?cache=pages&id=",
        "removeTemplateCache": "/content/admin/remove?cache=templates&id=",
        "fileTransferFolder": "/usr/local/tomcat/webapps/content/fileTransferFolder",
        "lookInContext": 1,
        "adminGroupID": 4,
        "betaServer": true}}],
  "servlet-mapping": {
    "cofaxCDS": "/",
    "cofaxEmail": "/cofaxutil/aemail/*",
    "cofaxAdmin": "/admin/*",
    "fileServlet": "/static/*",
    "cofaxTools": "/tools/*"},

  "taglib": {
    "taglib-uri": "cofax.tld",
    "taglib-location": "/WEB-INF/tlds/cofax.tld"}}}
```

IntelliSense now supports JSON Schema v3 and v4. There is a schema combo box to choose existing schemas, edit the local schema path, or simply drag drop a project JSON file to it to get the relative path.

```
http://json-schema.org/address
{
    "country-name": "USA",
    ""
}
```

country-name
extended-address
locality
postal-code
post-office-box
region
street-address

Type: String

- **New Sass (SCSS) editor**: We added LESS in VS2013 RTM, and we now have a Sass project item and editor. Sass editor features are comparable to the LESS editor, and include colorization, variable and Mixins IntelliSense, comment/uncomment, quick info, formatting, syntax validation, outlining, goto definition, color picker, tools option setting etc.

- **New URL Picker in HTML, Razor, CSS, LESS and Sass documents:** VS 2013 shipped with no URL picker outside of Web Forms pages. The new URL picker for HTML, Razor, CSS, LESS and Sass editors is a dialog-free, fluent typing picker that understands '..' and filters file lists appropriately for img tags and links.

- **Updates to LESS editor by adding more features**
- **Knockout Intellisense Upgrade**: We added a non-standard KnockOut syntax for VS intelliSense, "ko-vs-editor viewModel:" syntax. It can be used to bind to multiple view models on a page using comments in the form:

We also added support for nested ViewModel IntelliSense, so you may drill into deeply nested objects on the ViewModel.

```
<div data-bind="text: foo.bar.baz.etc" />
```

The IntelliSense displayed is the full IntelliSense of the JavaScript Object.

- **New URL Picker in HTML, Razor, CSS, LESS and Sass documents**: VS 2013 shipped with no URL picker outside of Web Forms pages. The new URL picker for HTML, Razor, CSS, LESS and Sass editors is a dialog-free, fluent typing picker that understands '..' and filters file lists appropriately for img tags and links.

Browser Link

- Browser Link now supports HTTPS connections and will list that in Dashboard with other connections as long as the certificate is trusted by browser.
- Static HTML source mapping
- SPA support for mapping data
- Auto-update mapping data

Support for Azure App Service Web Apps in Visual Studio

- **Support Azure sign in.**
- **Remote debugging and Remote View for web apps**: We now support remote debugging for web apps in Azure App Service and remote view of web app content files in the server explorer.

Create remote Azure resources when creating a new Web project

We added an Azure "Create Remote Resources" checkbox on the new web application dialog. By choosing it, you will be able to integrate the experience of creating a new web application, setting up the Azure publishing site for testing, and creating publishing profile in a few simple steps.

Web Publish Enhancements

- Improve User experience for publishing.

ASP.NET Scaffolding

- **Enum support:** If your model is using Enums, then the MVC Scaffolder will generate dropdown for Enum. This uses the Enum helpers in MVC.
- **Bootstrap support**: Updated the EditorFor templates in MVC Scaffolding so they use the Bootstrap classes.
- **Package support**: MVC and Web API Scaffolders will add 5.1 packages for MVC and Web API

The following screenshots demonstrate scaffolding models.

- Model code:

- Compile the model code, right-click, and select **Add**, **New Scaffolded Item**.

- Choose **MVC5 Controller with views, using Entity Framework**:

- **Add Controller** using the model:

- Check the generated code, for example Views/WeekdayModels/Edit.cshtml contains `@Html.EnumDropDownListFor`:

```
@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()

    <div class="form-horizontal">
        <h4>WeekdayModels</h4>
        <hr />
        @Html.ValidationSummary(true, "", new { @class = "text-danger" })
        @Html.HiddenFor(model => model.Identity)

        <div class="form-group">
            @Html.LabelFor(model => model.WeekDay, htmlAttributes: new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EnumDropDownListFor(model => model.WeekDay, htmlAttributes: new { @class = "form-control" })
                @Html.ValidationMessageFor(model => model.WeekDay, "", new { @class = "text-danger" })
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.WeekDayCanBeNull, htmlAttributes: new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EnumDropDownListFor(model => model.WeekDayCanBeNull, htmlAttributes: new { @class = "form-control" })
                @Html.ValidationMessageFor(model => model.WeekDayCanBeNull, "", new { @class = "text-danger" })
            </div>
        </div>

        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
}
```

- Run the page to see the enum combobox generated, notice that if a value can be null, an empty string can be chosen for the combo box. For example, the **Create** page shows the following:

NuGet 2.8.1

NuGet 2.8.1 RTM will be released in April 2014. Here are the salient points from the release notes, but please check the full release notes for more information on these changes.

- **Target Windows Phone 8.1 Applications**: NuGet 2.8.1 now supports targeting Windows Phone 8.1 Applications using the target framework monikers 'WindowsPhoneApp', 'WPA', 'WindowsPhoneApp81', and 'WPA81'.

- **Patch Resolution for Dependencies**: When resolving package dependencies, NuGet has historically implemented a strategy of selecting the lowest major and minor package version which satisfies the dependencies on the package. Unlike the major and minor version, however, the patch version was always resolved to the highest version. Though the behavior was well-intentioned, it created a lack of determinism for installing packages with dependencies.

- **DependencyVersion Switch**: Though NuGet 2.8 changes the *default* behavior for resolving dependencies, it also adds more precise control over dependency resolution process via the -DependencyVersion switch in the package manager console. The switch enables resolving dependencies to the lowest possible version (default behavior), the highest possible version, or the highest minor or patch version. This switch only works for install-package in the powershell command.

- **DependencyVersion Attribute**: In addition to the -DependencyVersion switch detailed above, NuGet has also allowed for the ability to set a new attribute in the nuget.config file defining what the default value is, if the -DependencyVersion switch is not specified in an invocation of install-package. This value will also be respected by the NuGet Package Manager Dialog for any install package operations. To set this value, add the attribute below to your nuget.config file:

  ```
  <config> <add key="dependencyversion" value="Highest" /> </config>
  ```

- **Preview NuGet Operations With -WhatIf**: Some NuGet packages can have deep dependency graphs, and as such, it can be helpful during an install, uninstall, or update operation to first see what will happen. NuGet 2.8 adds the standard PowerShell -what if switch to the install-package, uninstall-package, and update-package commands to enable visualizing the entire closure of packages to which the command will be applied.

- **Downgrade Package**: It is not uncommon to install a prerelease version of a package in order to investigate new features and then decide to roll back to the last stable version. Prior to NuGet 2.8, this was a multi-step process of uninstalling the prerelease package and its dependencies, and then installing the earlier version. With NuGet 2.8, however, the update-package will now roll back the entire package closure (e.g. the package's dependency tree) to the previous version.

- **Development Dependencies**: Many different types of capabilities can be delivered as NuGet packages - including tools that are used for optimizing the development process. These components, while they can be instrumental in developing a new package, should not be considered a dependency of the new package when it is later published. NuGet 2.8 enables a package to identify itself in the .nuspec file as a developmentDependency. When installed, this metadata will also be added to the packages.config file of the project into which the package was installed. When that packages.config file is later analyzed for NuGet dependencies during nuget.exe pack, it will exclude those dependencies marked as development dependencies.

- **Individual packages.config Files for Different Platforms**: When developing applications for multiple target platforms, it is common to have different project files for each of the respective build environments. It is also common to consume different NuGet packages in different project files, as packages have varying levels of support for different platforms. NuGet 2.8 provides improved support for this scenario by creating different packages.config files for different platform-specific project files.

- **Fallback to Local Cache**: Though NuGet packages are typically consumed from a remote gallery such as the NuGet gallery using a network connection, there are many scenarios where the client is not connected. Without a network connection, the NuGet client was not able to successfully install packages - even when those packages were already on the client's machine in the local NuGet cache. NuGet 2.8 adds automatic cache fallback to the package manager console.

  The cache fallback feature does not require any specific command arguments. Additionally, cache fallback currently works only in the package manager console - the behavior does not currently work in the package manager dialog.

- **Bug Fixes**: One of the major bug fixes made was performance improvement in the update-package -reinstall command.

  In addition to these features and the aforementioned performance fix, this release of NuGet also includes many other bug fixes. There were 181 total issues addressed in the release. For a full list of the work items

fixed in NuGet 2.8, please view the NuGet Issue Tracker for this release.

ASP.NET Web Forms

- The Web Forms templates now show how to do Account Confirmation and Password Reset for ASP.NET Identity.
- The Entity Data Source control and the Dynamic Data Provider for Entity Framework 6. For more details please see the following MSDN blog: Dynamic Data provider and EntityDataSource control for Entity Framework 6.

ASP.NET MVC 5.1.2

- Attribute Routing Improvements
- Bootstrap support for editor templates
- Enum support in views
- Unobtrusive support for MinLength/ MaxLength attributes
- Supporting the 'this' context in Unobtrusive Ajax
- Various bug fixes

ASP.NET Web API 2.1.2

- Global error handling
- Attribute routing enhancements
- Help page improvements
- IgnoreRoute support
- BSON media-type formatter
- Better support for async filters
- Query parsing for the client formatting library
- Various bug fixes

ASP.NET Web Pages 3.1.2

- Various bug fixes

Entity Framework 6.1

Entity Framework has been updated to version 6.1 for both runtime and tooling. Entity Framework (EF) 6.1 is a minor update to Entity Framework 6 and includes a number of bug fixes and new features. For detailed information on EF6.1, including links to documentation for the new features, see Entity Framework Version History. The new features in this release include:

- **Tooling consolidation** provides a consistent way to create a new EF model. This feature extends the ADO.NET Entity Data Model wizard to support creating Code First models, including reverse engineering from an existing database. These features were previously available in Beta quality in the EF Power Tools.
- **Handling of transaction commit failures** provides the new System.Data.Entity.Infrastructure.CommitFailureHandler which makes use of the newly introduced ability to intercept transaction operations. The **CommitFailureHandler** allows automatic recovery from connection failures whilst committing a transaction.
- **IndexAttribute** allows indexes to be specified by placing an attribute on a property (or properties) in your Code First model. Code First will then create a corresponding index in the database.
- **The public mapping API** provides access to the information EF has on how properties and types are mapped to columns and tables in the database. In past releases this API was internal.
- **Ability to configure interceptors via the App/Web.config file**(allowing interceptors to be added without recompiling the application).
- **DatabaseLogger** is a new interceptor that makes it easy to log all database operations to a file. In combination with the previous feature, this allows you to easily switch on logging of database operations for a deployed application, without the need to recompile.
- **Migrations model change detection** has been improved so that scaffolded migrations are more accurate;

performance of the change detection process has also been greatly enhanced.

- **Performance improvements** including reduced database operations during initialization, optimizations for null equality comparison in LINQ queries, faster view generation (model creation) in more scenarios, and more efficient materialization of tracked entities with multiple associations.

ASP.NET Identity 2.0.0

- **Two-factor authentication**: ASP.NET Identity now supports two-factor authentication. Two-factor authentication provides an extra layer of security to your user accounts in the case where your password gets compromised. There is also protection for brute force attacks against the two factor codes.
- **Account Lockout:** Provides a way to lock out the user if the user enters their password or two-factor codes incorrectly. The number of invalid attempts and the timespan for the users are locked out can be configured. A developer can optionally turn off Account Lockout for certain user accounts should they need to.
- **Account Confirmation:** The ASP.NET Identity system now supports Account Confirmation. This is a fairly common scenario in most websites today where, when you register for a new account on the website, you are required to confirm your email before you can do anything in the website. Email Confirmation is useful because it prevents bogus accounts from being created. This is extremely useful if you are using email as a method of communicating with the users of your website such as Forum sites, banking, ecommerce, or social web sites.
- **Password Reset:** Password Reset is a feature where the user can reset their passwords if they have forgotten their password.
- **Security Stamp (Sign out everywhere):** Supports a way to regenerate the Security Token for the user in cases when the User changes their password or any other security related information such as removing an associated login (such as Facebook, Google, Microsoft Account and so on). This is needed to ensure that any tokens generated with the old password are invalidated. In the sample project, if you change the user's password then a new token is generated for the user and any previous tokens are invalidated. This feature provides an extra layer of security to your application since when you change your password, you will be logged out from everywhere (all other browsers) where you have logged into this application.
- **Make the type of Primary Key be extensible for Users and Roles**: In ASP.NET Identity 1.0, the type of primary key for table Users and Roles was strings. This means when the ASP.NET Identity system was persisted in SQL Server by using Entity Framework, we were using nvarchar. There were many discussions around this default implementation on Stack Overflow and based on the incoming feedback. We have provided an extensibility hook where you can specify what should be the primary key of your Users and Roles table. This extensibility hook is particularly useful if you are migrating your application and the application was storing UserIds are GUIDs or ints.
- **Support IQueryable on Users and Roles**: Added support for IQueryable on UsersStore and RolesStore, you can easily get the list of Users and Roles.
- **Support Delete operation through the UserManager**
- **Indexing on UserName**: In ASP.NET Identity Entity Framework implementation, we have added a unique index on the Username by using the new IndexAttribute in EF 6.1.0. This makes sure that Usernames are always unique and there was no race condition in which you could end up with duplicate usernames.
- **Enhanced Password Validator:** The password validator that was shipped in ASP.NET Identity 1.0 was a fairly basic password validator that was only validating the minimum length. There is a new password validator that gives you more control over the complexity of the password. Please note that even if you turn on all the settings in this password, we do encourage you to enable two-factor authentication for the user accounts.
- **IdentityFactory Middleware/ CreatePerOwinContext**:

- **User Manager**: You can use Factory implementation to obtain an instance of UserManager from the OWIN context. This pattern is similar to what we use for getting AuthenticationManager from OWIN context for SignIn and SignOut. This is a recommended way of obtaining an instance of UserManager per request for the application.
- **DbContextFactory**: ASP.NET Identity uses Entity Framework for persisting the Identity system in SQL Server. To do this the Identity System has a reference to the ApplicationDbContext. The DbContextFactory Middleware returns an instance of the ApplicationDbContext per request that you can use in your application.

- **ASP.NET Identity Samples NuGet package**: The Samples NuGet package can make it easier to install and run samples for ASP.NET Identity and follow the best practices. This is a sample ASP.NET MVC application. Please modify the code to suit your application before you deploy this in production. The sample should be installed in an empty ASP.NET application. For more information about the package, go to the following blog post: Announcing RTM of ASP.NET Identity 2.0.0

Microsoft OWIN components

There were lots of bugs that were fixed in this release. Please see the release notes for the 2.1.0 release for more detailed information.

ASP.NET SignalR 2.0.2

There were lots of bugs that were fixed in this release. Please see the release notes for the 2.0.2 release for more detailed information.

Hands On Lab: Visual Studio 2013 Web Tools

2/20/2020 • 17 minutes to read • Edit Online

by Web Camps Team

Download Web Camps Training Kit

> Visual Studio is an excellent development environment for .NET-based Windows and web projects. It includes a powerful text editor that can easily be used to edit standalone files without a project.
>
> Visual Studio maintains a full-featured parse tree as you edit each file. This allows Visual Studio to provide unparalleled auto-completion and document-based actions while making the development experience much faster and more pleasant. These features are especially powerful in HTML and CSS documents.
>
> All of this power is also available for extensions, making it simple to extend the editors with powerful new features to suit your needs. Web Essentials is a collection of (mostly) web-related enhancements to Visual Studio. It includes lots of new IntelliSense completions (especially for CSS), new Browser Link features, automatic JSHint for JavaScript files, new warnings for HTML and CSS, and many other features that are essential to modern web development.
>
> All sample code and snippets are included in the Web Camps Training Kit, available at https://aka.ms/webcamps-training-kit.

Overview

Objectives

In this hands-on lab, you will learn how to:

- Use new HTML editor features included in Web Essentials such as rich HTML5 code snippets and Zen coding
- Use new CSS editor features included in Web Essentials such as the Color picker and Browser matrix tooltip
- Use new JavaScript editor features included in Web Essentials such as Extract to File and IntelliSense for all HTML elements
- Exchange data between your browser and Visual Studio using Browser Link

Prerequisites

The following is required to complete this hands-on lab:

- Microsoft Visual Studio Professional 2013 or greater
- Web Essentials 2013
- Google Chrome

Setup

In order to run the exercises in this hands-on lab, you will need to set up your environment first.

1. Open a Windows Explorer window and browse to the lab's **Source** folder.
2. Right-click **Setup.cmd** and select **Run as administrator** to launch the setup process that will configure your environment and install the Visual Studio code snippets for this lab.
3. If the User Account Control dialog box is shown, confirm the action to proceed.

> **NOTE**
> Make sure you have checked all the dependencies for this lab before running the setup.

Using the Code Snippets

Throughout the lab document, you will be instructed to insert code blocks. For your convenience, most of this code is provided as Visual Studio Code Snippets, which you can access from within Visual Studio 2013 to avoid having to add it manually.

> **NOTE**
> Each exercise is accompanied by a starting solution located in the **Begin** folder of the exercise that allows you to follow each exercise independently of the others. Please be aware that the code snippets that are added during an exercise are missing from these starting solutions and may not work until you have completed the exercise. Inside the source code for an exercise, you will also find an **End** folder containing a Visual Studio solution with the code that results from completing the steps in the corresponding exercise. You can use these solutions as guidance if you need additional help as you work through this hands-on lab.

Exercises

This hands-on lab includes the following exercises:

1. Working with Browser Link and Web Essentials
2. Taking Advantage of Code Snippets and IntelliSense

> **NOTE**
> When you first start Visual Studio, you must select one of the predefined settings collections. Each predefined collection is designed to match a particular development style and determines window layouts, editor behavior, IntelliSense code snippets, and dialog box options. The procedures in this lab describe the actions necessary to accomplish a given task in Visual Studio when using the **General Development Settings** collection. If you choose a different settings collection for your development environment, there may be differences in the steps that you should take into account.

Exercise 1: Working with Browser Link and Web Essentials

Web Essentials is a Visual Studio extension that adds a variety of useful features for modern web development, mostly focused on making the web development experience much faster and more pleasant. You can install Web Essentials from the Extension Gallery in Visual Studio.

Browser Link is a new feature included in Visual Studio 2013 that provides a channel between the Visual Studio IDE and any open browser to exchange data between your web application and Visual Studio. Web Essentials extends Browser Link with tools to manipulate the DOM object model and the CSS styles of your web pages directly from the browser.

In this exercise, you will explore some of the features supported by **Web Essentials** and **Browser Link** to enhance a simple quiz page.

Task 1 - Running the Project in Multiple Browsers

In this task, you will configure your web application to run in multiple browsers at once, which is useful for cross-browser testing.

1. Open **Microsoft Visual Studio**.
2. In the **File** menu, select **Open | Project/Solution...** and browse to **Ex1-**

WorkingwithBrowserLinkandWebEssentials\Begin in the **Source** folder of the lab (C:\WebCampsTK\HOL\VSWebTooling\Source). Select **Begin.sln** and click **Open**.

3. In the Visual Studio toolbar, expand the browser menu and select **Browse With...**.

Browse With menu option

4. In the **Browse With** dialog box, select both **Google Chrome** and **Internet Explorer** by holding down the **CTRL** key and click **Set as Default**.

Selecting multiple default browsers

5. Both Google Chrome and Internet Explorer should now appear as the default browsers. Click **Cancel** to close the dialog box.

Google Chrome and Internet Explorer as default browsers

NOTE

After configuring the default browsers, the **Multiple Browsers** option is selected in the browser menu.

6. Press **CTRL** + **F5** to run the application without debugging.
7. When both browser windows open, place one of them above the other in order to see the updates on both browsers simultaneously. The browsers should display a web page with a light-blue rectangle.

Placing one browser above the other

8. Do not close the browsers. You will use them in the next task.

Task 2 - Using Zen Coding to Create HTML Elements

Zen Coding is an editor plugin for high-speed HTML, XML, XSL (or any other structured code format) coding and editing. The core of this plugin is a powerful abbreviation engine which allows you to expand expressions -similar to CSS selectors- into HTML code. Zen Coding is a fast way to write HTML using a CSS style selector syntax.

In this exercise, you will use the Zen Coding feature provided by Web Essentials to generate the HTML buttons that represent the options of the question.

1. Switch back to Visual Studio.
2. Open the **Index.cshtml** file located in the **Views | Home** folder.
3. Replace the **<!-- TODO: add options here-->** comment with the following code, and press **TAB**.

```
button.btn.btn-info.btn-lg.option{Answer $}*4
```

4. The code should be expanded to HTML.

```
<section id="content">
    <div class="container">
        <div class="row">
            <div class="flip-container text-center col-md-12">
                <div class="front">
                    <div class="row text-center">
                        <button class="btn btn-info btn-lg option">Answer 1</button><button class="btn btn-info btn-lg option">Answer 2<
                    </div>
                </div>
            </div>
        </div>
    </div>
</section>
```

Expanded HTML

> **NOTE**
>
> To learn more about Zen Coding syntax, see the following article.

5. Click the **Refresh linked browsers** button to update both browsers.

Refresh linked browsers

Internet Explorer - Page updated with four buttons

Google Chrome - Page updated with four buttons

6. Switch back to Visual Studio.

7. You have added the buttons to the page, but you still need to add a template question. To do so, you will use a new feature in Web Essentials called **Lorem Ipsum generator**. Locate the **div** element with the **class** attribute **front**.

8. Add the following code as the first child element of the **div**, and press **TAB**.

```
p.lead>lorem5
```

9. The code should be expanded to HTML.

```
<section id="content">
    <div class="container">
        <div class="row">
            <div class="flip-container text-center col-md-12">
                <div class="front">
                    <p class="lead">
                        Lorem ipsum dolor sit amet.
                    </p>
                    <div class="row text-center">
                        <button class="btn btn-info btn-lg option">Answer 1</button><button class="btn
                    </div>
                </div>
            </div>
        </div>
    </div>
</section>
```

Lorem Ipsum autogenerated

> **NOTE**
>
> As part of Zen Coding, you can now generate Lorem Ipsum code directly in the HTML editor. Simply type **lorem** and hit **TAB** and a 30 word Lorem Ipsum text will be inserted. E.g. *lorem10* inserts 10 Lorem Ipsum words.

10. You will add a logo at the top of the question by using another new feature in Web Essentials called **Lorem Pixel generator**. Add the following code as the first child element of the **div** element with **container** as **class** value, and press **TAB**.

```
div.row.header>pix-436x185-abstract
```

11. The code should expand to HTML.

```
<section id="content">
    <div class="container">
        <div class="row header"><img src="http://lorempixel.com/436/185/abstract/3/" alt="" /></div>
        <div class="row">
            <div class="flip-container text-center col-md-12">
                <div class="front">
                    <p class="lead">
                        Lorem ipsum dolor sit amet.
                    </p>
                    <div class="row text-center">
                        <button class="btn btn-info btn-lg option">Answer 1</button><button class="btn btn-info btn-lg option">Answer 2</button><bu
                    </div>
                </div>
            </div>
        </div>
    </div>
</section>
```

Lorem Pixel autogenerated

> **NOTE**
>
> As part of Zen Coding, you can also generate Lorem Pixel code directly in the HTML editor. Simply type **pix-200x200-animals** and hit **TAB** and an **img** tag with a 200x200 image of an animal will be inserted. For more information, refer to Lorem Pixel.

12. Click the **Refresh linked browsers** button to update both browsers.

Internet Explorer - Autogenerated image and text

Google Chrome - Autogenerated image and text

> **NOTE**
>
> Because the image is selected randomly when adding the code snippet, the image shown in the browsers may differ.

13. Do not close the browsers. You will use them in the next task.

Task 3 - Updating a Style Property

In this task, you will use the Browser Link's **Inspect Mode** feature to detect the exact location where the specific DOM element is generated and then update the color property of that element using a color picker provided by Web Essentials.

1. In the Internet Explorer browser, press **CTRL** + **ALT** + **I** to enable Inspect Mode.

2. Move the pointer over the light blue border and click.

Moving the pointer over the light blue border

3. Switch back to Visual Studio. Notice how the HTML element that you selected in the browser is also selected in the Visual Studio HTML editor.

```
<section id="content">
    <div class="container">
        <div class="row header"><img src="http://lorempixel.com/436/185/abstract/1/" alt="" /></div>
        <div class="row">
            <div class="flip-container text-center col-md-12">
                <div class="front">
                    <p class="lead">
                        Lorem ipsum dolor sit amet.
                    </p>
                    <div class="row text-center">
                        <button class="btn btn-info btn-lg option">Answer 1</button><button class="btn btn-info btn-lg option">Answer 2</b
                    </div>
                </div>
            </div>
        </div>
    </div>
</section>
```

HTML element selected in the Visual Studio HTML editor

4. You will now update the **front** CSS class in order to change the styling of the selected element. To do so, press **CTRL** + **,** to open the **Navigate To** search box. Type **site.css** and press **ENTER** to open the file.

Opening file Site.css

5. Press **CTRL** + **F** and type **.flip-container .front** to find the CSS selector.

6. Click the light blue square in the border property of the class to open the Color Picker.

Opening the Color Picker

7. Expand the Color Picker by clicking the chevron button and select a new color.

Expanding the Color Picker

8. Press **CTRL** + **ALT** + **ENTER** to refresh linked browsers.

9. Switch to Internet Explorer and notice how the color of the border has changed.

Internet Explorer - Border color updated

10. Switch to Google Chrome and notice how the color of the border has changed.

Google Chrome - Border color updated

11. Switch back to Visual Studio.

12. Go to the end of the **Site.css** file and press **CTRL** + **F** to locate the **.btn** selector.

13. Notice that the **-webkit-border-radius** property is underlined in green.

```
.btn {
    -webkit-border-radius: 0px;
    word-wrap: break-word;
}

.header {
    background-color: #00bcf2;
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

-webkit-border-radius property of the btn selector

14. Place the caret in the **-webkit-border-radius** property. A blue line should appear under the first letter of the first word of the property. This is the **smart tag**.

15. Press **CTRL** + **.** to open the suggestions menu and click **Add missing standard property (border-radius)**.

```
.btn {
    -webkit-border-radius: 0px;
    wrap: break-word;
}
    Add missing standard property (border-radius)
.header {
    background-color: #00bcf2;
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

Add missing standard property suggestion

16. The **border-radius** property is automatically added to the CSS rule.

```
.btn {
    -webkit-border-radius: 0px;
    border-radius: 0px;
    word-wrap: break-word;
}

.header {
    background-color: #00bcf2;
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

Missing standard property added

17. Move the pointer over the **border-radius** property to display the **Browser matrix tooltip**. The **Browser matrix tooltip** shows the availability of the property in each browser.

```
.btn {
    -webkit-border-radius: 0px;
    border-radius: 0px;
}
    Example: td { border-radius: 3px 4px; }
    4  9  10.5  5
.hea
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

Browser matrix tooltip

18. Notice that the value of the **border-radius** property is still underlined. Move the pointer over the value to

see the warning message.

```
.btn {
    -webkit-border-radius: 0px;
    border-radius: 0px;
    word-wrap: brea
}

.header {
    background-color: #00bcf2;
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

Best Practice: Don't specify the unit type (px) when the value is zero. (Disable this check in Tools -> Options)

Border-radius property value warning

19. Remove the unit of the **border-radius** property value as suggested by the tooltip.

20. As **border-radius** is the standard property for defining how rounded border corners are, you can remove the **-webkit-border-radius** property and value from the CSS rule.

21. Place the caret in the **word-wrap** property and notice that the smart tag also appears below.

22. Open the menu and click **Add missing vendor specifics**.

```
.btn {
    border-radius: 0;
    word-wrap: break-word;
}

.hea
    background-color: #00bcf2;
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

Add missing vendor specifics

Add missing vendor specifics suggestion

23. The **-ms-word-wrap** property is automatically added to the CSS rule.

```
.btn {
    border-radius: 0;
    -ms-word-wrap: break-word;
    word-wrap: break-word;
}

.header {
    background-color: #00bcf2;
    margin-left: 0;
    margin-right: -30px;
    text-align: center;
}
```

Vendor specific property added

Task 4 - Updating the HTML Code from the Browser

In this task, you will use the Browser Link's **Design Mode** feature to edit the DOM object from the browser and transfer the changes to the HTML source file in Visual Studio.

1. In Google Chrome, press **CTRL** + **ALT** + **D** to enable Design Mode.

2. Move the pointer over the **Lorem Ipsum dolor sit amet** label and click.

Editing the question

3. A cursor should appear. Replace the original text with *What does it look like when I write a longer question?*, and then press **ESC** to exit Design Mode.

Question edited

4. Switch back to Visual Studio and open **Index.cshtml**, if not already opened. Notice that the inner text of the **<p>** element has been updated.

```
<section id="content">
    <div class="container">
        <div class="row header"><img src="http://lorempixel.com/436/185/abstract/1/" alt="" /></div>
        <div class="row">
            <div class="flip-container text-center col-md-12">
                <div class="front">
                    <p class="lead">What does it look like when I write a longer question?</p>
                    <div class="row text-center">
                        <button class="btn btn-info btn-lg option">Answer 1</button><button class="btn btn-infc
                    </div>
                </div>
            </div>
        </div>
    </div>
</section>
```

Updated question in the HTML page

Task 5 - Reviewing SEO Related Warnings

Search Engine Optimization (SEO) is the process of making a website rank higher on a search engine's list of results. The higher the site ranks and the more consistently it is listed, the more visitors the site will get from that search engine. Web Essentials incorporates an analytical tool that examines HTML, reports the issues found and provides assistance to fix them.

1. Go to the **View** menu and click **Error List** to open the **Error List** window.

Error List in View menu

2. Notice that there is an SEO warning notifying that a **<meta>** tag for the page description is missing. Double-click the SEO warning entry to fix it.

Error List window

3. In the **Web Essentials** dialog box, click **Yes** to insert a description <meta> tag.

Web Essentials dialog box

4. The editor for **_Layout.cshtml** opens and the **<meta>** tag is automatically added to the **head** section of the HTML file.

Meta tag automatically added to _Layout page

5. Change the value of the **content** attribute to *GeekQuiz* and save the file.

Exercise 2: Taking Advantage of Code Snippets and IntelliSense

With Web Essentials, the HTML editor has been extended with extra functionality. In this exercise, you will see some new features that are helpful when developing web applications.

Task 1 - Using IntelliSense in HTML Documents

The first new feature you will see in this task is called **Dynamic IntelliSense**. Dynamic IntelliSense reads other tags and attributes to infer the possible ids you will use.

In this task, you will create a new HTML form element which contains a label and an input field. Then you will add a **for** attribute to the label to bind it to the input, and you will see IntelliSense suggestions based on the ids of the inputs in scope.

1. Open **Visual Studio Express 2013 for Web** and the **Begin.sln** solution located in the **Source/Ex2-TakingAdvantageofCodeSnippetsandIntelliSense/Begin** folder. Alternatively, you can continue with the solution that you obtained in the previous exercise.

2. In **Solution Explorer**, open the **Index.cshtml** file located in the **Views | Home** folder.

3. Add the following form inside the **<section>** element.

   (Code Snippet - *VisualStudio2013WebTooling - Ex2 - Form*)

```
<form>
     <input type="text" id="name" />
</form>
```

4. The input tag should be preceded by a label with some description of the field. Add the following label before the input tag.

```
<form>
    <label id="name">Name</label>
    <input type="text" id="name" />
</form>
```

5. The **for** attribute of a **<label>** specifies which form element a label is bound to. The attribute's value should be equal to the id of the related element. Add the **for** attribute to the **<label>** element. As shown in the following figure, the "name" value pops up in the IntelliSense box, based on the id of the elements within the same scope (the enclosing **<form>**).

   Showing the id in IntelliSense

6. Delete the recently added **<form>** element and its content.

Task 2 - Using HTML Code Snippets

HTML5 introduced more than 25 new semantic tags. Visual Studio already had IntelliSense support for these tags, but Visual Studio 2013 makes it faster and easier to write markup by adding new code snippets. Though these tags are not complicated, they come with a few small subtleties, such as adding the correct codec fallbacks for the *audio* tag. In this task, you will see the HTML code snippets for the audio tag.

1. In the **Index.cshtml** file, type **<aud** inside the **<section>** element as shown in the following figure.

```
<section id="content">
    <div class="container">
        <div class="row header"><img src="http://lorempixel.com/436/185/abstract/1/" alt="" /></div>
        <div class="row">
            <div class="flip-container text-center col-md-12">
                <div class="front">
                    <p class="lead">What does it look like when I write a longer question?</p>
                    <div class="row text-center">
                        <button class="btn btn-info btn-lg option">Answer 1</button><button class="btn btn-info btn-lg option">A
                    </div>
                </div>
            </div>
        </div>
    </div>
    <aud
</sec audio
```

Inserting an audio element

2. Press **TAB** twice and notice how the following code is added on the page and the cursor is placed on the **src** attribute of the first source.

```
<audio controls="controls">
     <source src="file.mp3" type="audio/mp3" />
     <source src="file.ogg" type="audio/ogg" />
</audio>
```

> **NOTE**
>
> By pressing the **TAB** key twice, the code snippet is inserted. The audio snippet shows the standard usage of the *audio* tag, with two source files for improved support.

3. Delete the second line and update the source of the first line with the following link to the WebCampsTV Katana show: http://media.ch9.ms/ch9/11d8/604b8163-fad3-4f12-9607-b404201211d8/KatanaProject.mp3. The resulting code is shown below.

```
<audio controls="controls">
     <source src="http://media.ch9.ms/ch9/11d8/604b8163-fad3-4f12-9607-b404201211d8/KatanaProject.mp3"
type="audio/mp3" />
</audio>
```

> **NOTE**
>
> The source file *KatanaProject.mp3* is used as an example. You can use another source if you prefer.

4. Press **CTRL** + **S** to save the file.

5. Press **CTRL** + **F5** to start the application.

6. Notice that an audio player was added to the application.

Audio player in Internet Explorer

Audio player in Google Chrome

7. Do not close the browsers. You will use them in the next task.

Task 3 - Using IntelliSense in JavaScript Documents

With Web Essentials 2013, style sheets and HTML pages produce a list of IDs and class names. In this task, you will learn how those lists improve JavaScript IntelliSense support in Web Essentials 2013.

1. In the **Index.cshtml** file, add the following code to define a **script** tag for JavaScript code.

```
...
</section>
@section scripts{
    <script type="text/javascript">

    </script>
}
```

2. Add the following code inside the **script** tag to define the ready callback function.

   (Code Snippet - *VisualStudio2013WebTooling - Ex2 - ReadyFunction*)

```
(function () {
    $(document).ready(function () {

    });
}());
```

3. Place the caret in the **script** tag and press **CTRL** + . to open the suggestion menu.

4. Click **Extract To File**.

JavaScript extract to file suggestion

5. In the **Save As** window, select the **Scripts** folder, name the file **init.js** and click **Save**.

Save As window

NOTE

The **init.js** file is created and the content of the script is moved to the file.

Init.js file created with the content included

6. Open the **Index.cshtml** file and check that the script tag was replaced with a reference to the **init.js** file.

```
    </audio>
</section>

@section scripts{
    <script src="/Scripts/init.js"></script>
}
```

Init.js html reference

7. Go to the **Solution Explorer** and notice that the **init.js** file was included automatically in the solution.

Init.js file included in solution

8. Switch back to the **init.js** file to update the **ready** function callback.

9. Inside the function callback definition that is passed to *ready*, add the following code to get all the elements by a specific class attribute.

```
(function () {
    $(document).ready(function () {
        document.getElementsByClassName("")
    });
}());
```

10. Press **CTRL** + **Space** between the quotes inside the **getElementsByClassName** function call.

```
1 (function () {
2     $(document).ready(function () {
3         document.getElementsByClassName("")
4     });
5 }());
```

NodeList getElementsByClassName(**String classNames**)

"active"
"affix"
"alert"
"alert-danger"
"alert-dismissable"
"alert-info"
"alert-link"
"alert-success"
"alert-warning"

Showing IntelliSense for the getElementsByClassName function

> **NOTE**
>
> Notice that IntelliSense shows the classes defined in the project style sheets.

11. Replace the line that you have created with the following code.

```
(function () {
    $(document).ready(function () {
        var audioElements = document.getElementsByTagName("au");
    });
}());
```

12. Position the cursor after **au** inside the quotes in the **getElementsByTagName** function and press **CTRL** + **Space**.

```
(function () {
    $(document).ready(function () {
        var audioElements = document.getElementsByTagName("au");
    });
}());
```

"animateTransform"
"area"
"article"
"aside"
"audio"
"b"
"bdi"
"bdo"
"blockquote"

Showing IntelliSense for the getElementsByTagName method

13. Select **"audio"** from the list and press **ENTER**. The result is shown in the following figure.

```
1 (function () {
2     $(document).ready(function () {
3         var audioElements = document.getElementsByTagName("audio");
4     });
5 }());
```

Retrieving Audio Elements

14. In **Solution Explorer**, right-click the **init.js** file in the **Scripts** folder and select **Minify JavaScript file(s)** from the **Web Essentials** menu.

Minify JavaScript file(s)

15. When prompted to enable automatic minification when the source file changes click **Yes**.

Enabling automatic minification warning

NOTE

The **init.min.js** is created and is added as a dependency of the **init.js** file.

Init.min.js file created

16. Open the **init.min.js** file and notice that the file is minified.

```
init.min.js   init.js   Index.cshtml
(function(){$(document).ready(function(){var n=document.getElementsByTagName("audio")})})();
/*
//# sourceMappingURL=init.min.js.map
*/
```

Init.min.js file content

17. In the **init.js** file, add the following code below the **getElementsByTagName** function call to play all the audio elements.

(Code Snippet - *VisualStudio2013WebTooling - Ex2 - PlayAudioElements*)

```
var len = audioElements.length;
for (var i = 0; i < len; i++) {
    audioElements[i].play();
}
```

18. Click **CTRL** + **S** to save the file. Since the minified file is already opened, you will see a dialog box saying that the file was modified outside of the source editor. Click **Yes**.

Microsoft Visual Studio warning

19. Switch back to the **init.min.js** file to verify that the file was updated with the new code.

```
init.min.js   init.js   Index.cshtml
(function(){$(document).ready(function(){for(var t=document.getElementsByTagName("audio"),i=t.length,n=0;n<i;n++)t[n].play()})})();
/*
//# sourceMappingURL=init.min.js.map
*/
```

Init.min.js file updated

20. Click the **Browser Link Refresh** button.

21. Once both browsers are refreshed the audio players you saw in the previous task will start playing automatically.

Audio player included in view

Summary

By completing this hands-on lab you have learned how to:

- Use new HTML editor features included in Web Essentials such as rich HTML5 code snippets and Zen coding
- Use new CSS editor features included in Web Essentials such as the Color picker and Browser matrix tooltip
- Use new JavaScript editor features included in Web Essentials such as Extract to File and IntelliSense for all HTML elements
- Exchange data between your browser and Visual Studio using Browser Link

Hands On Lab: One ASP.NET: Integrating ASP.NET Web Forms, MVC and Web API

2/20/2020 • 18 minutes to read • Edit Online

by Web Camps Team

Download Web Camps Training Kit

> ASP.NET is a framework for building Web sites, apps and services using specialized technologies such as MVC, Web API and others. With the expansion ASP.NET has seen since its creation and the expressed need to have these technologies integrated, there have been recent efforts in working towards **One ASP.NET**.
>
> Visual Studio 2013 introduces a new unified project system which lets you build an application and use all the ASP.NET technologies in one project. This feature eliminates the need to pick one technology at the start of a project and stick with it, and instead encourages the use of multiple ASP.NET frameworks within one project.
>
> All sample code and snippets are included in the Web Camps Training Kit, available at https://aka.ms/webcamps-training-kit.

Overview

Objectives

In this hands-on lab, you will learn how to:

- Create a Web site based on the **One ASP.NET** project type
- Use different **ASP.NET** frameworks like **MVC** and **Web API** in the same project
- Identify the main components of an **ASP.NET** application
- Take advantage of the **ASP.NET Scaffolding** framework to automatically create Controllers and Views to perform CRUD operations based on your model classes
- Expose the same set of information in machine- and human-readable formats using the right tool for each job

Prerequisites

The following is required to complete this hands-on lab:

- Visual Studio Express 2013 for Web or greater
- Visual Studio 2013 Update 1

Setup

In order to run the exercises in this hands-on lab, you will need to set up your environment first.

1. Open Windows Explorer and browse to the lab's **Source** folder.
2. Right-click on **Setup.cmd** and select **Run as administrator** to launch the setup process that will configure your environment and install the Visual Studio code snippets for this lab.
3. If the User Account Control dialog box is shown, confirm the action to proceed.

> **NOTE**
>
> Make sure you have checked all the dependencies for this lab before running the setup.

Using the Code Snippets

Throughout the lab document, you will be instructed to insert code blocks. For your convenience, most of this code is provided as Visual Studio Code Snippets, which you can access from within Visual Studio 2013 to avoid having to add it manually.

> **NOTE**
>
> Each exercise is accompanied by a starting solution located in the **Begin** folder of the exercise that allows you to follow each exercise independently of the others. Please be aware that the code snippets that are added during an exercise are missing from these starting solutions and may not work until you have completed the exercise. Inside the source code for an exercise, you will also find an **End** folder containing a Visual Studio solution with the code that results from completing the steps in the corresponding exercise. You can use these solutions as guidance if you need additional help as you work through this hands-on lab.

Exercises

This hands-on lab includes the following exercises:

1. Creating a New Web Forms Project
2. Creating an MVC Controller Using Scaffolding
3. Creating a Web API Controller Using Scaffolding

Estimated time to complete this lab: **60 minutes**

> **NOTE**
>
> When you first start Visual Studio, you must select one of the predefined settings collections. Each predefined collection is designed to match a particular development style and determines window layouts, editor behavior, IntelliSense code snippets, and dialog box options. The procedures in this lab describe the actions necessary to accomplish a given task in Visual Studio when using the **General Development Settings** collection. If you choose a different settings collection for your development environment, there may be differences in the steps that you should take into account.

Exercise 1: Creating a New Web Forms Project

In this exercise you will create a new Web Forms site in Visual Studio 2013 using the **One ASP.NET** unified project experience, which will allow you to easily integrate Web Forms, MVC and Web API components in the same application. You will then explore the generated solution and identify its parts, and finally you will see the Web site in action.

Task 1 – Creating a New Site Using the One ASP.NET Experience

In this task you will start creating a new Web site in Visual Studio based on the **One ASP.NET** project type. **One ASP.NET** unifies all ASP.NET technologies and gives you the option to mix and match them as desired. You will then recognize the different components of Web Forms, MVC and Web API that live side by side within your application.

1. Open **Visual Studio Express 2013 for Web** and select **File | New Project...** to start a new solution.

Creating a New Project

2. In the **New Project** dialog box, select **ASP.NET Web Application** under the **Visual C# | Web** tab, and make sure **.NET Framework 4.5** is selected. Name the project *MyHybridSite*, choose a **Location** and click **OK**.

Creating a new ASP.NET Web Application project

3. In the **New ASP.NET Project** dialog box, select the **Web Forms** template and select the **MVC** and **Web API** options. Also, make sure that the **Authentication** option is set to **Individual User Accounts**. Click **OK** to continue.

Creating a new project with the Web Forms template, including Web API and MVC components

4. You can now explore the structure of the generated solution.

Exploring the generated solution

a. **Account:** This folder contains the Web Form pages to register, log in to and manage the application's user accounts. This folder is added when the **Individual User Accounts** authentication option is selected during the configuration of the Web Forms project template.
b. **Models:** This folder will contain the classes that represent your application data.
c. **Controllers** and **Views**: These folders are required for the **ASP.NET MVC** and **ASP.NET Web API** components. You will explore the MVC and Web API technologies in the next exercises.
d. The **Default.aspx**, **Contact.aspx** and **About.aspx** files are pre-defined Web Form pages that you can use as starting points to build the pages specific to your application. The programming logic of those files resides in a separate file referred to as the "code-behind" file, which has an ".aspx.vb" or ".aspx.cs" extension (depending on the language used). The code-behind logic runs on the server and dynamically produces the HTML output for your page.
e. The **Site.Master** and **Site.Mobile.Master** pages define the look and feel and the standard behavior of all the pages in the application.

5. Double-click the **Default.aspx** file to explore the content of the page.

```
Default.aspx
<%@ Page Title="Home Page" Language="C#" MasterPageFile="~/Site.Master"
    AutoEventWireup="true" CodeBehind="Default.aspx.cs" Inherits="MyHybridSite._Default" %>

<asp:Content ID="BodyContent" ContentPlaceHolderID="MainContent" runat="server">

    <div class="jumbotron">
        <h1>ASP.NET</h1>
        <p class="lead">ASP.NET is a free web framework for building great Web sites and Web applications
        <p><a href="http://www.asp.net" class="btn btn-primary btn-large">Learn more &raquo;</a></p>
    </div>

    <div class="row">
        <div class="col-md-4">
            <h2>Getting started</h2>
            <p>
                ASP.NET Web Forms lets you build dynamic websites using a familiar drag-and-drop, event-d
            A design surface and hundreds of controls and components let you rapidly build sophisticated,
            </p>
            <p>
                <a class="btn btn-default" href="http://go.microsoft.com/fwlink/?LinkId=301948">Learn mor
            </p>
        </div>
        <div class="col-md-4">
            <h2>Get more libraries</h2>
```

Exploring the Default.aspx page

> **NOTE**
>
> The **Page** directive at the top of the file defines the attributes of the Web Forms page. For example, the **MasterPageFile** attribute specifies the path to the master page -in this case, the *Site.Master* page- and the **Inherits** attribute defines the code-behind class for the page to inherit. This class is located in the file determined by the **CodeBehind** attribute.
>
> The **asp:Content** control holds the actual content of the page (text, markup and controls) and is mapped to a **asp:ContentPlaceHolder** control on the master page. In this case, the page content will be rendered inside the *MainContent* control defined in the *Site.Master* page.

6. Expand the **App_Start** folder and notice the **WebApiConfig.cs** file. Visual Studio included that file in the generated solution because you included Web API when configuring your project with the One ASP.NET template.

7. Open the **WebApiConfig.cs** file. In the *WebApiConfig* class you will find the configuration associated with Web API, which maps HTTP routes to **Web API controllers**.

```
public static void Register(HttpConfiguration config)
{
    // Web API configuration and services

    // Web API routes
    config.MapHttpAttributeRoutes();

    config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );
}
```

8. Open the **RouteConfig.cs** file. Inside the *RegisterRoutes* method you will find the configuration associated with MVC, which maps HTTP routes to **MVC controllers**.

```
public static void RegisterRoutes(RouteCollection routes)
{
    var settings = new FriendlyUrlSettings();
    settings.AutoRedirectMode = RedirectMode.Permanent;
    routes.EnableFriendlyUrls(settings);

    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
            name: "Default",
            url: "{controller}/{action}/{id}",
            defaults: new { action = "Index", id = UrlParameter.Optional }
        );
}
```

Task 2 – Running the Solution

In this task you will run the generated solution, explore the app and some of its features, like URL rewriting and built-in authentication.

1. To run the solution, press **F5** or click the **Start** button located on the toolbar. The application home page should open in the browser.

2. Verify that the Web Forms pages are being invoked. To do this, append **/contact.aspx** to the URL in the address bar and press **Enter**.

Friendly URLs

> **NOTE**
>
> As you can see, the URL changes to **/contact**. Starting from **ASP.NET 4**, URL routing capabilities were added to Web Forms, so you can write URLs like *http://www.mysite.com/products/software* instead of *http://www.mysite.com/products.aspx?category=software*. For more information refer to URL Routing.

3. You will now explore the authentication flow integrated into the application. To do this, click **Register** in the upper-right corner of the page.

Registering a new user

4. In the **Register** page, enter a **User name** and **Password**, and then click **Register**.

Register page

5. The application registers the new account, and the user is authenticated.

User authenticated

6. Go back to Visual Studio and press **SHIFT + F5** to stop debugging.

Exercise 2: Creating an MVC Controller Using Scaffolding

In this exercise you will take advantage of the ASP.NET Scaffolding framework provided by Visual Studio to create an ASP.NET MVC 5 controller with actions and Razor views to perform CRUD operations, without writing a single line of code. The scaffolding process will use Entity Framework Code First to generate the data context and the database schema in the SQL database.

About Entity Framework Code First

Entity Framework (EF) is an object-relational mapper (ORM) that enables you to create data access applications by programming with a conceptual application model instead of programming directly using a relational storage schema.

The Entity Framework Code First modeling workflow allows you to use your own domain classes to represent the model that EF relies on when performing querying, change-tracking and updating functions. Using the Code First development workflow, you do not need to begin your application by creating a database or specifying a schema. Instead, you can write standard .NET classes that define the most appropriate domain model objects for your application, and Entity Framework will create the database for you.

> **NOTE**
>
> You can learn more about Entity Framework here.

Task 1 – Creating a New Model

You will now define a **Person** class, which will be the model used by the scaffolding process to create the MVC controller and the views. You will start by creating a **Person** model class, and the CRUD operations in the controller will be automatically created using scaffolding features.

1. Open **Visual Studio Express 2013 for Web** and the **MyHybridSite.sln** solution located in the **Source/Ex2-MvcScaffolding/Begin** folder. Alternatively, you can continue with the solution that you obtained in the previous exercise.

2. In **Solution Explorer**, right-click the **Models** folder of the **MyHybridSite** project and select **Add | Class...**.

Adding the Person model class

3. In the **Add New Item** dialog box, name the file *Person.cs* and click **Add**.

Creating the Person model class

4. Replace the content of the **Person.cs** file with the following code. Press **CTRL + S** to save the changes.

   (Code Snippet - *BringingTogetherOneAspNet - Ex2 - PersonClass*)

```
namespace MyHybridSite.Models
{
    public class Person
    {
        public int Id { get; set; }

        public string Name { get; set; }

        public int Age { get; set; }
    }
}
```

5. In **Solution Explorer**, right-click the **MyHybridSite** project and select **Build**, or press **CTRL + SHIFT + B** to build the project.

Task 2 – Creating an MVC Controller

Now that the **Person** model is created, you will use ASP.NET MVC scaffolding with Entity Framework to create the CRUD controller actions and views for **Person**.

1. In **Solution Explorer**, right-click the **Controllers** folder of the **MyHybridSite** project and select **Add | New Scaffolded Item...**.

Creating a new Scaffolded Controller

2. In the **Add Scaffold** dialog box, select **MVC 5 Controller with views, using Entity Framework** and then click **Add**.

Selecting MVC 5 Controller with views and Entity Framework

3. Set *MvcPersonController* as the **Controller name**, select the **Use async controller actions** option and select **Person (MyHybridSite.Models)** as the **Model class**.

Adding an MVC controller with scaffolding

4. Under **Data context class**, click **New data context...**.

Creating a new data context

5. In the **New Data Context** dialog box, name the new data context *PersonContext* and click **Add**.

Creating the new PersonContext type

6. Click **Add** to create the new controller for **Person** with scaffolding. Visual Studio will then generate the controller actions, the Person data context and the Razor views.

After creating the MVC controller with scaffolding

7. Open the **MvcPersonController.cs** file in the **Controllers** folder. Notice that the CRUD action methods have been generated automatically.

```
...

// POST: /MvcPerson/Create
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see https://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Create([Bind(Include="Id,Name,Age")] Person person)
{
     if (ModelState.IsValid)
     {
          db.People.Add(person);
          await db.SaveChangesAsync();
          return RedirectToAction("Index");
     }

     return View(person);
}

// GET: /MvcPerson/Edit/5
public async Task<ActionResult> Edit(int? id)
{
     if (id == null)
     {
          return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
     }
     Person person = await db.People.FindAsync(id);
     if (person == null)
     {
          return HttpNotFound();
     }
     return View(person);
}

...
```

> **NOTE**
>
> By selecting the **Use async controller actions** check box from the scaffolding options in the previous steps, Visual Studio generates asynchronous action methods for all actions that involve access to the Person data context. It is recommended that you use asynchronous action methods for long-running, non-CPU bound requests to avoid blocking the Web server from performing work while the request is being processed.

Task 3 – Running the Solution

In this task, you will run the solution again to verify that the views for **Person** are working as expected. You will add a new person to verify that it is successfully saved to the database.

1. Press **F5** to run the solution.

2. Navigate to **/MvcPerson**. The scaffolded view that shows the list of people should appear.

3. Click **Create New** to add a new person.

Navigating to the scaffolded MVC views

4. In the **Create** view, provide a **Name** and an **Age** for the person, and click **Create**.

Adding a new person

5. The new person is added to the list. In the element list, click **Details** to display the person's details view. Then, in the **Details** view, click **Back to List** to go back to the list view.

Person's details view

6. Click the **Delete** link to delete the person. In the **Delete** view, click **Delete** to confirm the operation.

Deleting a person

7. Go back to Visual Studio and press **SHIFT + F5** to stop debugging.

Exercise 3: Creating a Web API Controller Using Scaffolding

The Web API framework is part of the ASP.NET Stack and designed to make implementing HTTP services easier, generally sending and receiving JSON- or XML-formatted data through a RESTful API.

In this exercise, you will use ASP.NET Scaffolding again to generate a Web API controller. You will use the same **Person** and **PersonContext** classes from the previous exercise to provide the same person data in JSON format. You will see how you can expose the same resources in different ways within the same ASP.NET application.

Task 1 – Creating a Web API Controller

In this task you will create a new **Web API Controller** that will expose the person data in a machine-consumable format like JSON.

1. If not already opened, open **Visual Studio Express 2013 for Web** and open the **MyHybridSite.sln**

solution located in the **Source/Ex3-WebAPI/Begin** folder. Alternatively, you can continue with the solution that you obtained in the previous exercise.

> **NOTE**
>
> If you start with the Begin solution from Exercise 3, press **CTRL + SHIFT + B** to build the solution.

2. In **Solution Explorer**, right-click the **Controllers** folder of the **MyHybridSite** project and select **Add | New Scaffolded Item...**.

Creating a new scaffolded Controller

3. In the **Add Scaffold** dialog box, select **Web API** in the left pane, then **Web API 2 Controller with actions, using Entity Framework** in the middle pane and then click **Add**.

Selecting Web API 2 Controller with actions and Entity Framework

4. Set *ApiPersonController* as the **Controller name**, select the **Use async controller actions** option and select **Person (MyHybridSite.Models)** and **PersonContext (MyHybridSite.Models)** as the **Model** and **Data context** classes respectively. Then click **Add**.

Adding a Web API controller with scaffolding

5. Visual Studio will then generate the **ApiPersonController** class with the four CRUD actions to work with your data.

After creating the Web API controller with scaffolding

6. Open the **ApiPersonController.cs** file and inspect the *GetPeople* action method. This method queries the db field of **PersonContext** type in order to get the people data.

```
// GET api/ApiPerson
public IQueryable<Person> GetPeople()
{
    return db.People;
}
```

7. Now notice the comment above the method definition. It provides the URI that exposes this action which you will use in the next task.

```
// GET api/ApiPerson
public IQueryable<Person> GetPeople()
{
    return db.People;
}
```

> **NOTE**
>
> By default, Web API is configured to catch the queries to the */api* path to avoid collisions with MVC controllers. If you need to change this setting, refer to Routing in ASP.NET Web API.

Task 2 – Running the Solution

In this task you will use the Internet Explorer **F12 developer tools** to inspect the full response from the Web API controller. You will see how you can capture network traffic to get more insight into your application data.

> **NOTE**
>
> Make sure that **Internet Explorer** is selected in the **Start** button located on the Visual Studio toolbar.
>
> >
>
> The **F12 developer tools** have a wide set of functionality that is not covered in this hands-on-lab. If you want to learn more about it, refer to Using the F12 developer tools.

1. Press **F5** to run the solution.

> **NOTE**
>
> In order to follow this task correctly, your application needs to have data. If your database is empty, you can go back to Task 3 in Exercise 2 and follow the steps on how to create a new person using the MVC views.

2. In the browser, press **F12** to open the **Developer Tools** panel. Press **CTRL + 4** or click the **Network** icon, and then click the green arrow button to begin capturing network traffic.

Initiating Web API network capture

3. Append **api/ApiPerson** to the URL in the browser's address bar. You will now inspect the details of the response from the **ApiPersonController**.

Retrieving person data through Web API

> **NOTE**
>
> Once the download finishes, you will be prompted to make an action with the downloaded file. Leave the dialog box open in order to be able to watch the response content through the Developers Tool window.

4. Now you will inspect the body of the response. To do this, click the **Details** tab and then click **Response body**. You can check that the downloaded data is a list of objects with the properties **Id**, **Name** and **Age** that correspond to the **Person** class.

Viewing Web API Response Body

Task 3 – Adding Web API Help Pages

When you create a Web API, it is useful to create a help page so that other developers will know how to call your API. You could create and update the documentation pages manually, but it is better to auto-generate them to avoid having to do maintenance work. In this task you will use a Nuget package to automatically generate Web API help pages to the solution.

1. From the **Tools** menu in Visual Studio, select **NuGet Package Manager**, and then click **Package Manager Console**.

2. In the **Package Manager Console** window, execute the following command:

```
Install-Package Microsoft.AspNet.WebApi.HelpPage
```

> **NOTE**
>
> The **Microsoft.AspNet.WebApi.HelpPage** package installs the necessary assemblies and adds MVC Views for the help pages under the **Areas/HelpPage** folder.

HelpPage Area

3. By default, the help pages have placeholder strings for documentation. You can use XML documentation comments to create the documentation. To enable this feature, open the **HelpPageConfig.cs** file located in the **Areas/HelpPage/App_Start** folder and uncomment the following line:

```
config.SetDocumentationProvider(new
XmlDocumentationProvider(HttpContext.Current.Server.MapPath("~/App_Data/XmlDocument.xml")));
```

4. In **Solution Explorer**, right-click the project **MyHybridSite**, select **Properties** and click the **Build** tab.

Build tab

5. Under **Output**, select **XML documentation file**. In the edit box, type **App_Data/XmlDocument.xml**.

Output section in Build tab

6. Press **CTRL + S** to save the changes.

7. Open the **ApiPersonController.cs** file from the **Controllers** folder.

8. Enter a new line between the *GetPeople* method signature and the *// GET api/ApiPerson* comment, and then type three forward slashes.

> **NOTE**
>
> Visual Studio automatically inserts the XML elements which define the method documentation.

9. Add a summary text and the return value for the *GetPeople* method. It should look like the following.

```
// GET api/ApiPerson
/// <summary>
/// Documentation for 'GET' method
/// </summary>
/// <returns>Returns a list of people in the requested format</returns>
public IQueryable<Person> GetPeople()
{
    return db.People;
}
```

10. Press **F5** to run the solution.

11. Append **/help** to the URL in the address bar to browse to the help page.

ASP.NET Web API Help Page

> **NOTE**
>
> The main content of the page is a table of APIs, grouped by controller. The table entries are generated dynamically, using the **IApiExplorer** interface. If you add or update an API controller, the table will be automatically updated the next time you build the application.
>
> The **API** column lists the HTTP method and relative URI. The **Description** column contains information that has been extracted from the method's documentation.

12. Note that the description you added above the method definition is displayed in the description column.

API method description

13. Click one of the API methods to navigate to a page with more detailed information, including sample

response bodies.

Detailed information page

Summary

By completing this hands-on lab you have learned how to:

- Create a new Web application using the One ASP.NET Experience in Visual Studio 2013
- Integrate multiple ASP.NET technologies into one single project
- Generate MVC controllers and views from your model classes using ASP.NET Scaffolding
- Generate Web API controllers, which use features such as Async Programming and data access through Entity Framework

- Automatically generate Web API Help Pages for your controllers

Release Notes for ASP.NET and Web Tools 2013.1 for Visual Studio 2012

4/10/2020 • 6 minutes to read • Edit Online

by Microsoft

This document describes the release of ASP.NET and Web Tools 2013.1 for Visual Studio 2012.

Contents

- Installation Notes
- Software Requirements
- New Features in ASP.NET and Web Tools 2013.1 for Visual Studio 2012
  - Bootstrap
  - Templates
    - ASP.NET MVC 5 template
    - ASP.NET Web API 2 template
    - Item Templates
  - Entity Framework 6
  - ASP.NET Scaffolding
  - Razor Editor
  - NuGet 2.7
- Known Issues and Breaking Changes
  - ASP.NET Scaffolding
    - MVC and Web API Scaffolding - HTTP 404, Not Found error
    - Visual Studio Express 2012 for Web stops working after adding a scaffolded item
  - ASP.NET Razor 3
    - Viewing cshtml file with Browse With or F5 causes a server error
    - Url Rewrite and Tilde(~)
  - Templates

Installation Notes

Install ASP.NET and Web Tools 2013.1 for Visual Studio 2012.

Software Requirements

You must have either Visual Studio 2012 or Visual Studio Express 2012 for Web.

New Features in ASP.NET and Web Tools 2013.1 for Visual Studio 2012

Bootstrap

When you scaffold MVC 5 controllers and views, the markup for the views uses Bootstrap.

Templates

ASP.NET MVC 5 template

We added a new MVC 5 template. It references the latest MVC 5 NuGet packages, and you can use scaffolding to add controllers and views.

ASP.NET Web API 2 template

We added a new Web API 2 template. It references the latest Web API 2 NuGet packages, and you can use scaffolding to add controllers and views.

Item Templates

We added new item templates for MVC 5 views, Web Pages (Razor 3), and Web API 2 controllers. They install the related NuGet packages to the project while adding new items.

Entity Framework 6

When you scaffold an MVC or Web API controller using Entity Framework, we use Framework 6. For more information about Entity Framework, see the Entity Framework Version History.

You can also download and install the Entity Framework 6 Tools for Visual Studio 2012. See the Get Entity Framework.

ASP.NET Scaffolding

ASP.NET Scaffolding is a code generation framework for ASP.NET Web applications. It makes it easy to add boilerplate code to your project that interacts with a data model.

In previous versions of Visual Studio, scaffolding was limited to ASP.NET MVC projects. With this update, you can now use scaffolding for any ASP.NET project, including Web Forms. This update does not support generating pages for a Web Forms project, but you can still use scaffolding with Web Forms by adding MVC dependencies to the project. Support for generating pages for Web Forms will be added in a future update.

When using scaffolding, we ensure that all required dependencies are installed in the project. For example, if you start with an ASP.NET Web Forms project and then use scaffolding to add a Web API Controller, the required NuGet packages and references are added to your project automatically.

To add MVC scaffolding to a Web Forms project, add a **New Scaffolded Item** and select **MVC 5 Dependencies** in the dialog window. There are two options for scaffolding MVC; Minimal and Full. If you select Minimal, only the NuGet packages and references for ASP.NET MVC are added to your project. If you select the Full option, the Minimal dependencies are added, as well as the required content files for an MVC project.

Support for scaffolding async controllers uses the new async features from Entity Framework 6.

For more information and tutorials, see ASP.NET Scaffolding Overview. These tutorials show scaffolding with Visual Studio 2013, but they are also applicable to ASP.NET and Web Tools 2013.1 for Visual Studio 2012.

Razor Editor

With this update, Visual Studio 2012 now supports Razor 3 tooling/editing.

NuGet 2.7

NuGet 2.7 includes a rich set of new features which are described in detail at NuGet 2.7 Release Notes.

This version of NuGet removes the need for users to explicitly allow NuGet to restore missing packages. When installing NuGet 2.7, users implicitly consent to automatically restoring missing packages. Users can explicitly opt out of package restoration through the NuGet settings in Visual Studio. This change simplifies how package restoration works.

Known Issues and Breaking Changes

ASP.NET Scaffolding

MVC and Web API Scaffolding - HTTP 404, Not Found error

If you encounter an error when adding a scaffolded item to a project, it is possible your project will be left in an inconsistent state. Some of the changes made be scaffolding will be rolled back but other changes, such as the installed NuGet packages, will not be rolled back. If the routing configuration changes are rolled back, users will receive an HTTP 404 error when navigating to scaffolded items.

To fix this error for MVC, add a new scaffolded item and select MVC 5 Dependencies (either Minimal or Full). This process will add all of the required changes to your project.

To fix this error for Web API:

1. Add the following WebApiConfig class to your project.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.MapHttpAttributeRoutes();
        config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );
    }
}
```

```
Public Module WebApiConfig
    Public Sub Register(ByVal config As HttpConfiguration)
        config.MapHttpAttributeRoutes()
        config.Routes.MapHttpRoute(
          name:="DefaultApi",
          routeTemplate:="api/{controller}/{id}",
          defaults:=New With {.id = RouteParameter.Optional}
        )
    End Sub
End Module
```

2. Configure WebApiConfig.Register in the Application_Start method in Global.asax as follows:

```
public class WebApiApplication : System.Web.HttpApplication
{
    protected void Application_Start()
    {
        GlobalConfiguration.Configure(WebApiConfig.Register);
    }
}
```

```
Public Class WebApiApplication
     Inherits System.Web.HttpApplication

     Sub Application_Start()
       GlobalConfiguration.Configure(AddressOf WebApiConfig.Register)
     End Sub
End Class
```

Visual Studio Express 2012 for Web stops working after adding a scaffolded item

If Visual Studio Express 2012 for Web stops working after adding scaffolded item with Entity Framework (such as Web API 2 Controller with actions, using Entity Framework), it is possible that Visual Studio Express failed to load the native image of an assembly dependent on System.Web.Extensions.

To correct this problem, configure Visual Studio Express to work with the MSIL image of System.Web.Extensions:

1. Open Command Prompt in the Administrator mode.
2. Go to %ProgramFiles%\Microsoft Visual Studio 11.0\Common7\IDE or %ProgramFiles(x86)%\Microsoft Visual Studio 11.0\Common7\IDE (for 64 bit Windows).
3. Open VWDExpress.exe.config in a text editor.
4. Add the following line under the <configuration>/<runtime> element:

```
<disableNativeImageLoad>
    <assemblyIdentity name="System.Web.Extensions" />
</disableNativeImageLoad>
```

5. Restart Visual Studio Express 2012 for Web.

ASP.NET Razor 3

Viewing cshtml file with Browse With or F5 causes a server error

When you create an MVC 5 project in Visual Studio 2012 (or open in Visual Studio 2012 an MVC 5 project that was created in Visual Studio 2013) and attempt to view a cshtml file by using Browse With or F5, you will receive an error that states - **Server Error in '/' Application**. The server attempts to navigate to `http://localhost:XXXX/Views/../XXXX.cshtml`

To resolve this issue, change the **Start Action** setting in your project to **Specific Page**. You do not need to provide a value for the page.

After making this change, selecting F5 navigates to the root of your application (`http://localhost:XXXX`). This behavior is not the same as the behavior for MVC 5 projects in Visual Studio 2013, where the **Current Page** setting launches the open page.

Url Rewrite and Tilde(~)

After upgrading to ASP.NET Razor 3 or ASP.NET MVC 5, the tilde(~) notation may no longer work correctly if you are using URL rewrites. The URL rewrite affects the tilde(~) notation in HTML elements such as <A/>, <SCRIPT/>, <LINK/>, and as a result the tilde no longer maps to the root directory.

For example, if you rewrite requests for **asp.net/content** to **asp.net**, the href attribute in <A href="~/content/"/> resolves to **/content/content/** instead of **/**. To suppress this change, you can set the **IIS_WasUrlRewritten** context to false in each Web Page or in **Application_BeginRequest** in Global.asax.

Templates

When you create ASP.NET MVC projects with Visual Studio 2012 on Windows 8.1 or Windows Server 2012 R2, Visual Studio displays an error message that states "Configuring Web [url] for ASP.NET 4.5 failed."

You see this error because Visual Studio 2012 does not enable the ASP.NET 4.5 feature when it is installed on those releases of Windows. To enable ASP.NET 4.5, perform the steps described in Turn Windows features on or off.

Alternatively, you can enable ASP.NET 4.5 through the command line.

1. Open Command Prompt in the Administrator mode.
2. Run the following command to enable ASP.NET 4.5.

```
dism /Online /Enable-Feature /FeatureName:NetFx4Extended-ASPNET45 /Quiet /NoRestart
```

Windows Azure Authentication

9/16/2020 • 6 minutes to read • Edit Online

by Rick Anderson

Microsoft ASP.NET tools for Windows Azure Active Directory makes it simple to enable authentication for web applications hosted on Windows Azure Web Sites. You can use Windows Azure Authentication to authenticate Office 365 users from your organization, corporate accounts synced from your on-premise Active Directory or users created in your own custom Windows Azure Active Directory domain. Enabling Windows Azure Authentication configures your application to authenticate users using a single Windows Azure Active Directory tenant.

The ASP.NET Windows Azure Authentication tool is not supported for web roles in a cloud service but we plan to do so in a future release. Windows Identity Foundation (WIF) is supported in Windows Azure web roles.

For details on how to setup synchronization between your on-premise Active Directory and your Windows Azure Active Directory tenant please see Use AD FS 2.0 to implement and manage single sign-on.

Windows Azure Active Directory is currently available as a free preview service.

Requirements:

- Visual Studio 2012 or Visual Studio Express 2012
- Web Tools Extensions for Visual Studio 2012 or Web Tools Extensions for Visual Studio Express 2012
- Microsoft ASP.NET Tools for Windows Azure Active Directory – Visual Studio 2012 or Microsoft ASP.NET Tools for Windows Azure Active Directory – Visual Studio Express 2012 for Web

Create an ASP.NET Web Application with Visual Studio 2012

You can create any Web Application with Visual Studio 2012, this tutorial uses the ASP.NET MVC intranet template.

1. Create a new ASP.NET MVC 4 Intranet Application and accept all the defaults. (It must be an In **tra** net and not In **ter** net project).

Enable Window Azure Authentication (When you are a Global Administrator of the Tenet)

If you do not have an existing Windows Azure Active Directory tenant (For example, through an existing Office 365 account) you can create a new tenant by signing up for a new Windows Azure Active Directory account.

1. From the Project menu select **Enable Windows Azure Authentication**:

2. Enter the domain for your Windows Azure Active Directory tenant (for example, contoso.onmicrosoft.com) and click **Enable**:

3. In the Web Authentication dialog sign in as an administrator for your Windows Azure Active Directory tenant:

Enable Window Azure by a non-administrator of the Tenet

If you do not have Global Administrator privilege for your Windows Azure Active Directory tenant, you can uncheck the checkbox for provisioning the application.

The dialog will display the **Domain**, **Application Principal Id** and **Reply URL** which are required for provisioning the application with an Azure Active Directory tenet. You need to give this information to someone who has sufficient privilege to provision the application. SeeHow to implement single sign-on with Windows

Azure Active Directory - ASP.NET Application for details on how to use cmdlet to create the service principal manually. Once the application has been successfully provisioned, you can click on **Continue to update web.config with the selected settings**. If you want to continue developing the application while waiting for provisioning to happen, you can click **Close to remember the settings in project file**. The next time you invoke Enable Windows Azure Authentication and uncheck the provisioning checkbox, you will see the same settings and you can click **Continue**, then click, **Apply these settings in web.config**.

1. Wait while your application is configured for Windows Azure Authentication and provisioned with Windows Azure Active Directory.

2. Once Windows Azure Authentication has been enabled for your application, click **Close:**

3. Hit F5 to run your application. You should automatically get redirected to login page. Use the directory tenet user credentials to login to the application..

4. Because your application is currently using a self-signed test certificate you will receive a warning from the browser that the certificate was not issued by a trusted certificate authority.

   This warning can be safely ignored during local development by clicking **Continue to this website:**

5. You have now successfully logged in to your application using Windows Azure Authentication!

Enabling Windows Azure authentication makes the following changes to your application:

- An Anti-Cross-Site Request Forgery (CSRF) class (*App_Start\AntiXsrfConfig.cs*) is added to your project.
- The NuGet packages `System.IdentityModel.Tokens.ValidatingIssuerNameRegistry` is added to your project.
- Windows Identity Foundation settings in your application will be configured to accept security tokens from your Windows Azure Active Directory tenant. Click on the image below to see an expanded view of the changes made to the *Web.config* file.

```
9     <section name="entityFramework" type="System.Data.Entity.
10    <section name="system.identityModel" type="System.Identit
11    <section name="system.identityModel.services" type="Syste
12  </configSections>
18    <add key="UnobtrusiveJavaScriptEnabled" value="true" />
19    <add key="ida:FederationMetadataLocation" value="https://
20    <add key="ida:ProviderSelection" value="productionSTS" />
21    <add key="enableSimpleMembership" value="false" />
22  </appSettings>
23  <location path="FederationMetadata">
24    <system.web>
25      <authorization>
26        <allow users="*" />
27      </authorization>
28    </system.web>
29  </location>
30  <system.web>
31    <authentication mode="None" />
32    <compilation debug="true" targetFramework="4.5" />
33    <httpRuntime targetFramework="4.5" requestValidationMode=
34    <!--Commented out by Windows Azure Authentication tool-->
35    <!--<authentication mode="Windows" />-->
61    </handlers>
62    <modules>
63      <add name="WSFederationAuthenticationModule" type="Sy...
64      <add name="SessionAuthenticationModule" type="System.
65    </modules>
66  </system.webServer>
67  <runtime>
92    </defaultConnectionFactory>
93  </entityFramework>
94  <system.identityModel>
95    <identityConfiguration>
96      <audienceUris>
97        <add value="spn:b63b9031-7d95-4bd0-b4ea-edadd1
```

- A service principal for your application in your Windows Azure Active Directory tenant will be provisioned.
- HTTPS is enabled.

Deploy the application to Windows Azure

For complete instructions, see Deploying an ASP.NET Web Application to a Windows Azure Web Site.

To publish an application using Windows Azure Authentication to an Azure Web Site:

1. Right click on your application and select **Publish:**

2. From the Publish Web dialog download and import a publishing profile for your Azure Web Site.

3. The **Connection** tab shows the **Destination URL** (the public facing URL for your application). Click **Validate Connection** to test your connection:

4. If you have published to this Azure Web Site previously consider checking the **Remove additional files at destination** setting to ensure your application publishes cleanly. Notice the **Enable Windows Azure Authentication** check box is selected.

5. Optional: On the **Preview** tab click **Start Preview** to see the files deployed.

6. Click **Publish**.

   You will be prompted to enable Windows Azure Authentication for the target host. Click **Enable** to continue:

7. Enter your administrator credentials for your Windows Azure Active Directory tenant:

8. Once your application has been successfully published, a browser will open to the published web site.

> **NOTE**
>
> It may take up to five minutes (typically must less) for your application to be fully provisioned with Windows Azure Active Directory after enabling Windows Azure Authentication for the target host. When you first run your application if you receive error ACS50001: Relying party with name '[realm]' was not found, then wait a few minutes and try running the application again.

9. When prompted, log in as a user in your directory:

10. You have now successfully logged into your Azure hosted application using Windows Azure Authentication.

Known Issues

Role-based authorization fails when using Windows Azure Authentication

Windows Azure Authentication does not currently provide the necessary role claim so that role-based authorization can be performed. The role of the authenticated user must be manually retrieved from Windows Azure Active Directory.

Browsing to an application with Windows Azure Authentication results in the error "ACS20016 The domain of the logged in user (live.com) does not match any allowed domain of this STS"

If you are already logged in to a Microsoft Account (for example hotmail.com, live.com, outlook.com) and you attempt to access an application that has enabled Windows Azure Authentication you may get a 400 error response because the domain of your Microsoft Account is not recognized by Windows Azure Active Directory. To log into the application, log out from your Microsoft Account first.

Logging into an application with Windows Azure Authentication enabled and a X509CertificateValidationMode other than None results in certificate validation errors for the accounts.accesscontrol.windows.net certificate

Certificate validation is not required and should be left disabled. The thumbprint of the issuer certificate is validated by the WSFederationAuthenticationModule.

When attempting to enable Windows Azure Authentication the Web Authentication dialog shows the error "ACS20016: The domain of the logged in user (contoso.onmicrosoft.com) does not match any allowed domain of this STS."

You may see this error when you have previously successfully logged in using a different Windows Azure Active Directory account from within the same Visual Studio process. Log out from the specified account or restart Visual Studio. If you previously logged in and selected the option to "Keep me signed in" then you may need to clear your browser cookies.

ACS20012: The request is not a valid WS-Federation protocol message

This can happen if you are already logged in with some other Microsoft ID to one of the Azure services. Use Private browser window like InPrivate in IE or Incognito in Chrome or clear all the cookies.

ASP.NET and Web Tools 2012.2 Release Notes

2/20/2020 • 11 minutes to read • Edit Online

This document describes the release of ASP.NET and Web Tools 2012.2. It is an update to Visual Studio Web Tooling and ASP.NET.

- Installation Notes
- Documentation
- Support
- Software Requirements
- New Features in ASP.NET and Web Tools 2012.2
  - Tooling
  - Web Publishing
  - ASP.NET MVC Templates
  - ASP.NET Web API
  - ASP.NET SignalR
  - ASP.NET Friendly URLs
- Known Issues and Breaking Changes

Installation Notes

ASP.NET and Web Tools 2012.2 for Visual Studio 2012 can be installed using Web Platform installer. This is an update to Visual Studio 2012 or Visual Studio Express 2012 for Web, which is required. If you do not have Visual Studio installed, Visual Studio Express 2012 for Web will be installed.

You can also install ASP.NET and Web Tools 2012.2 manually. You must have Visual Studio 2012 or Visual Studio Express 2012 for Web installed. Then use the following instructions:

1. Download ASP.NET and Web Frameworks 2012.2 installer from Download Center.
2. When prompted click Run. You can also save the file to run it later.
3. Verify the version of Visual Studio you will update. You can do this by launching the Visual Studio you wish to update. Then click the Help menu item.

4. If you see the menu item "About Microsoft Visual Studio 2012 for Web" then download Web Developer Tools 2012.2 - Visual Studio Express 2012 for Web. Otherwise download Web Developer Tools 2012.2 - Visual Studio 2012.
5. When prompted click Run. You can also save the file to run it later.

> **NOTE**
> ASP.NET and Web Tools 2012.2 release does not include SQL Server Data Tools. SQL Server and Windows Azure SQL Databases provides a richer set of database tooling including offline project-backed development, schema comparison and enhanced database deployment capabilities. For more information or to install SQL Server Data Tools visit https://go.microsoft.com/fwlink/?LinkID=237127.

Documentation

Tutorials and other information about ASP.NET and Web Tools 2012.2 are available from ASP.NET web site (https://www.asp.net).

Support

ASP.NET and Web Tools 2012.2 is officially released and supported. You can use your normal support channel. You can also post questions to the ASP.NET forums (https://forums.asp.net/), where members of the ASP.NET community are frequently able to provide informal support.

Software Requirements

The ASP.NET and Web Tools 2012.2 requires Visual Studio 2012 or Visual Studio Express 2012 for Web.

New Features in ASP.NET and Web Tools 2012.2

This section describes features that have been introduced in the ASP.NET and Web Tools 2012.2 release.

Tooling

- Page Inspector
  - Support JavaScript selection mapping allowing Page Inspector to map items that were dynamically added to the page back to the corresponding JavaScript code.
  - The ability to see CSS updates in real-time.
  - For more information, read CSS Auto-Sync and JavaScript Selection Mapping in Page Inspector.
- Editor

  - Support syntax highlighting for CoffeeScript, Mustache, Handlebars, and JsRender.
  - The HTML editor provides Intellisense for Knockout bindings.
  - LESS editing and compiler support to enable building dynamic CSS using LESS.
  - Paste JSON as a .NET class. Using this Special Paste command to paste JSON into a C# or VB.NET code file, and Visual Studio will automatically generate .NET classes inferred from the JSON.
- Mobile Emulator support adds extensibility hooks so that third-party emulators can be installed as a VSIX. The installed emulators will show up in the F5 dropdown, so that developers can preview their websites on a variety of mobile devices. Read more about this feature in Scott Hanselman's blog entry on the new BrowserStack integration with Visual Studio.

Web Publishing

- Web site projects now have the same publishing experience as Web Application projects including publishing to Windows Azure Web Sites.
- Selective publish – for one or more files you can perform the following actions (after publishing to a Web Deploy endpoint):
  - Publish selected files.
  - See the difference between a local file and a remote file.
  - Update the local file with the remote file or update the remote file with the local file.

ASP.NET MVC Templates

- The new Facebook Application template makes writing Facebook Canvas applications easy. In a few simple steps, you can create a Facebook application that gets data from a logged in user and integrates with their friends. The template includes a new library to take care of all the plumbing involved in building a Facebook app, including authentication, permissions, accessing Facebook data and more. For more information on using the Facebook Application template see https://go.microsoft.com/fwlink/?LinkID=269921.
- A new Single Page Application MVC template allows developers to build interactive client-side web apps using HTML 5, CSS 3, and the popular Knockout and jQuery JavaScript libraries, on top of ASP.NET Web API. The template includes a "todo" list application that demonstrates common practices for building a JavaScript HTML5 application that uses a RESTful server API. You can read more at https://www.asp.net/single-page-application.
- You can now create a VSIX that adds new templates to the ASP.NET MVC New Project dialog. Learn how here: https://go.microsoft.com/fwlink/?LinkId=275019
- FixedDisplayModes package – MVC project templates have been updated to include the new 'FixedDisplayModes' NuGet package, which contains a workaround for a bug in MVC 4. For more information on the fix contained in the package, refer to this blog post (https://blogs.msdn.com/b/rickandy/archive/2012/09/17/asp-net-mvc-4-mobile-caching-bug-fixed.aspx) from the MVC team.

ASP.NET Web API

ASP.NET Web API has been enhanced with several new features:

- ASP.NET Web API OData
- ASP.NET Web API Tracing
- ASP.NET Web API Help Page

ASP.NET Web API OData

ASP.NET Web API OData gives you the flexibility you need to build OData endpoints with rich business logic over any data source. With ASP.NET Web API OData you control the amount of OData semantics that you want to expose. ASP.NET Web API OData is included with the ASP.NET MVC 4 project templates and is also available from NuGet (http://www.nuget.org/packages/microsoft.aspnet.webapi.odata).

ASP.NET Web API OData currently supports the following features:

- Enable OData query semantics by applying the [Queryable] attribute.
- Easily validate OData queries and restrict the set of supported query options, operators and functions.
- Parameter bind to ODataQueryOptions directly to get an abstract syntax tree representation of the query that can then be validated and applied to an IQueryable or IEnumerable.
- Enable service-driven paging and next page link generation by specifying result limits on [Queryable] attribute.
- Request an inlined count of the total number of matching resources using $inlinecount.
- Control null propagation.
- Any/All operators in $filter.
- Infer an entity data model by convention or explicitly customize a model in a manner similar to Entity Framework Code-First.
- Expose entity sets by deriving from EntitySetController.
- Simple, customizable conventions for exposing navigation properties, manipulating links and implementing OData actions.
- Simplified routing using the MapODataRoute extension method.
- Support for versioning by exposing multiple EDM models.
- Expose service document and $metadata so you can generate clients (.NET, Windows Phone, Windows Store, etc.) for your Web API.
- Support for the OData Atom, JSON, and JSON verbose formats.
- Create, update, partially update (PATCH) and delete entities.
- Query and manipulate relationships between entities.
- Create relationship links that wire up to your routes.
- Complex types.
- Entity Type Inheritance.
- Collection properties.
- Enums.
- OData actions.
- Built upon the same foundation as WCF Data Services, namely ODataLib (http://www.nuget.org/packages/microsoft.data.odata).

For more information on ASP.NET Web API OData see https://go.microsoft.com/fwlink/?LinkId=271141.

ASP.NET Web API Tracing

ASP.NET Web API Tracing integrates tracing data from your web APIs with .NET Tracing. It is now enabled by default in the Web API project template. Tracing data for your web APIs is sent to the Output window and is made available through IntelliTrace. ASP.NET Web API Tracing enables you to trace information about your Web API when hosted on Windows Azure through integration with Windows Azure Diagnostics. You can also install and enable ASP.NET Web API Tracing in any application using the ASP.NET Web API Tracing NuGet package (http://www.nuget.org/packages/microsoft.aspnet.webapi.tracing).

For more information on configuring and using ASP.NET Web API Tracing see https://go.microsoft.com/fwlink/?LinkID=269874.

ASP.NET Web API Help Page

The ASP.NET Web API Help Page is now included by default in the Web API project template. The ASP.NET Web API Help Page automatically generates documentation for web APIs including the HTTP endpoints, the supported HTTP methods, parameters and example request and response message payloads. Documentation is automatically pulled from comments in your code. You can also add the ASP.NET Web API Help Page to any application using the ASP.NET Web API Help Page NuGet package (http://www.nuget.org/packages/microsoft.aspnet.webapi.helppage).

For more information on setting up and customizing the ASP.NET Web API Help Page see https://go.microsoft.com/fwlink/?LinkId=271140.

ASP.NET SignalR

ASP.NET SignalR makes it simple to add real-time web capabilities to your ASP.NET application, using WebSockets if available and automatically falling back to other techniques when it isn't.

For more information on using ASP.NET SignalR see https://go.microsoft.com/fwlink/?LinkId=271271.

ASP.NET Friendly URLs

ASP.NET FriendlyURLs makes it very easy for web forms developers to generate cleaner looking URLs(without the .aspx extension). It requires little to no configuration and can be used with existing ASP.NET v4.0 applications. The FriendlyURLs feature also makes it easier for developers to add mobile support to their applications, by supporting switching between desktop and mobile views.

For more information on installing and using ASP.NET Friendly URLs see http://www.hanselman.com/blog/IntroducingASPNETFriendlyUrlsCleanerURLsEasierRoutingAndMobileViewsForASPNETWebForms.aspx.

Known Issues and Breaking Changes

This section describes known issues and breaking changes that are in the ASP.NET and Web Tools 2012.2 release.

Installation Issues

Out of order installs of Visual Studio 2012

Installing an additional SKU of Visual Studio 2012 after installing the ASP.NET and Web Tools 2012.2 will require a repair operation. Consider the following sequence:

1. Install Visual Studio 2012 Express for Web
2. Install ASP.NET and Web Tools 2012.2
3. Install Visual Studio 2012 Professional, Premium or Ultimate

Step 2 would only result in installing updates for Express for Web. To ensure that the additional SKU installed during step 3 contains the update you will need to repair the ASP.NET and Web Tools 2012.2 to install the updates for the last SKU installed. This also applies if the SKUs in Step 1 and 3 are reversed.

Installing Microsoft ASP.NET and Web Tools 2012.2 when Visual Studio is open

If VS is open during installation of Microsoft ASP.NET and Web Tools 2012.2, Visual Studio might end up in a bad state. It is recommended that users close all instances of Visual Studio before proceeding with install.

Canceling ASP.NET and Web Tools 2012.2 setup in the middle of installation

Canceling ASP.NET and Web Tools 2012.2 setup in the middle of installation will leave Visual Studio in a bad state. To address this problem follow these steps:

- Go to Add Remove Programs
- Uninstall Microsoft ASP.NET and Web Tools 2012.2, if present.
- Reinstall Microsoft ASP.NET and Web Tools 2012.2

After uninstalling ASP.NET and Web Tools 2012.2 the ASP.NET MVC 4 templates and Razor v2 Web Site templates are missing

Uninstalling ASP.NET and Web Tools 2012.2 will also uninstall all of ASP.NET MVC 4 and Razor v2 Web Site templates from Visual Studio 2012.

The workaround is to repair your Visual Studio 2012 installation to reinstall ASP.NET MVC 4 and Razor v2 Web Site templates.

Tooling Issues

NuGet error reported during project creation

After installing ASP.NET and Web Tools 2012.2 you may see the following error when creating an MVC 4 project

The ASP.NET and Web Tools 2012.2 ships NuGet 2.1 and will upgrade the extension in Visual Studio 2012. In some cases, the VSIX installer will fail to correctly update the VSIX. The following steps will allow you to address this problem:

1. Start Visual Studio 2012 as an Administrator
2. Go to Tools->Extensions and Updates and uninstall NuGet.
3. Close Visual Studio
4. Navigate to the ASP.NET and Web Tools 2012.2 installation folder:
   a. For Visual Studio 2012: **Program Files\Microsoft ASP.NET\ASP.NET Web Stack\Visual Studio 2012**
   b. For Visual Studio 2012 Express for Web: **Program Files\Microsoft ASP.NET\ASP.NET Web Stack\Visual Studio Express 2012 for Web**
5. Double click on the NuGet.Tools.vsix to reinstall NuGet

Web API Issues

Parsing issues in $filter and DateTime literals

The OData URI parser fails to parse partial datetime literals properly. For example, $filter=start eq datetime'2012-12-31T12:00' fails to parse properly. A workaround is to use the full literal, $filter=start eq datetime'2012-12-31T12:00:00'.

OData doesn't support case-insensitive property names.

OData doesn't support case-insensitive property names in OData queries and odata path. See workitems:

- http://aspnetwebstack.codeplex.com/workitem/366
- http://aspnetwebstack.codeplex.com/workitem/704

If users have different casing on javascript client side and server side, they probably will encounter this issue. This issue is by design in odata protocol. However, many users reports this issue. To work around it, users have to correct their cases in URL.

Default OData routing conventions doesn't support POST/PUT on navigation property.

Default OData routing conventions doesn't support POST/PUT on navigation property. See workitem http://aspnetwebstack.codeplex.com/workitem/366. We are missing this commonly used convention in default conventions.

To work around it, users need to extend new routing convention to support it.

Facebook Template Issues

Facebook Application template only works using .NET 4.5

You must select .NET 4.5 in the framework dropdown list in the New Project dialog to see the Facebook Application template in ASP.NET MVC 4.

Real-time Update Controller

The Facebook Application template allows user easily create a Web API Controller to handle real-time updates from

Facebook. If your development machine is behind NAT, your Controller may not work without further network configuration. See here for details: http://facebook.stackoverflow.com/questions/5259467/can-a-computer-behind-a-nat-router-receive-realtime-updates-from-facebook

Query string values conflict with Facebook OAuth parameters

The following fields conflict with Facebook OAuth dialog's call back URL. Do not add your own query string values with the following names: code, error, error_description, error_reason.

Using Page Inspector with Facebook Template

You can't use the Page Inspector feature in Visual Studio 2012 while debugging your Facebook Application. The Page Inspector does not currently support iframes.

Single Page Application Template Issues

With JQuery 1.9/Knockout 2.2.1 update, when running default MVC SPA project, new todo item edit enter focus event is not handled properly.

With JQuery 1.9/Knockout 2.2.1 update, when running default MVC SPA project, new todo item edit enter no longer focus back to the new todo item edit box after entering the new todo item to the todo list.

To workaround reference http://knockoutjs.com/documentation/hasfocus-binding.html, and make similar fix to the following sample code:

File todo.model.js
function todolist(data), add following:
self.isSelected = ko.observable(false);

function todoList.prototype.addTodo, add the following blacked text:
self.isSelected(true);
self.newTodoTitle("");

File index.cshtml, add the following blacked text:
<form data-bind="submit: addTodo">
<input class="addTodo" type="text" data-bind="value: newTodoTitle, placeholder: 'Type here to add', blurOnEnter: true, **hasfocus: isSelected**, event: { blur: addTodo }" />
</form>

Entity Framework

2/20/2020 • 2 minutes to read • Edit Online

Entity Framework (EF) is an object-relational mapper that enables .NET developers to work with relational data using domain-specific objects. It eliminates the need for most of the data-access code that developers usually need to write.

- Get it: Add this to your project and start taking advantage of this powerful O/RM.
- Get Started: Visit the guide for videos and tutorials that will help you make the most of your data.
- Get Help: Find out how to get help from the experts and contribute to the data community on Stack Overflow.
- Contribute: Find out how you can help make Entity Framework, an open development model, even better by visiting GitHub site.

Getting Started with ASP.NET Identity

2/20/2020 • 2 minutes to read • Edit Online

The ASP.NET Identity system is designed to replace the previous ASP.NET Membership and Simple Membership systems. It includes profile support, OAuth integration, works with OWIN, and is included with the ASP.NET templates shipped with Visual Studio 2013.

- Introduction to ASP.NET Identity
- ASP.NET Identity Recommended Resources
- Adding ASP.NET Identity to an Empty or Existing Web Forms Project
- Developing ASP.NET Apps with Azure Active Directory
- ASP.NET Identity: Using MySQL Storage with an EntityFramework MySQL Provider (C#)

Introduction to ASP.NET Identity

2/20/2020 • 10 minutes to read • Edit Online

The ASP.NET membership system was introduced with ASP.NET 2.0 back in 2005, and since then there have been many changes in the ways web applications typically handle authentication and authorization. ASP.NET Identity is a fresh look at what the membership system should be when you are building modern applications for the web, phone, or tablet.

Background: Membership in ASP.NET

ASP.NET Membership

ASP.NET Membership was designed to solve site membership requirements that were common in 2005, which involved Forms Authentication, and a SQL Server database for user names, passwords, and profile data. Today there is a much broader array of data storage options for web applications, and most developers want to enable their sites to use social identity providers for authentication and authorization functionality. The limitations of ASP.NET Membership's design make this transition difficult:

- The database schema was designed for SQL Server and you can't change it. You can add profile information, but the additional data is packed into a different table, which makes it difficult to access by any means except through the Profile Provider API.
- The provider system enables you to change the backing data store, but the system is designed around assumptions appropriate for a relational database. You can write a provider to store membership information in a non-relational storage mechanism, such as Azure Storage Tables, but then you have to work around the relational design by writing much code and a lot of `System.NotImplementedException` exceptions for methods that don't apply to NoSQL databases.
- Since the log-in/log-out functionality is based on Forms Authentication, the membership system can't use OWIN. OWIN includes middleware components for authentication, including support for log-ins using external identity providers (like Microsoft Accounts, Facebook, Google, Twitter), and log-ins using organizational accounts from on-premises Active Directory or Azure Active Directory. OWIN also includes support for OAuth 2.0, JWT and CORS.

ASP.NET Simple Membership

ASP.NET simple membership was developed as a membership system for ASP.NET Web Pages. It was released with WebMatrix and Visual Studio 2010 SP1. The goal of Simple Membership was to make it easy to add membership functionality to a Web Pages application.

Simple Membership did make it easier to customize user profile information, but it still shares the other problems with ASP.NET Membership, and it has some limitations:

- It was hard to persist membership system data in a non-relational store.
- You can't use it with OWIN.
- It doesn't work well with existing ASP.NET Membership providers, and it's not extensible.

ASP.NET Universal Providers

ASP.NET Universal Providers were developed to make it possible to persist membership information in Microsoft Azure SQL Database, and they also work with SQL Server Compact. The Universal Providers were built on Entity Framework Code First, which means that the Universal Providers can be used to persist data in any store supported by EF. With the Universal Providers, the database schema was cleaned up quite a lot as well.

The Universal Providers are built on the ASP.NET Membership infrastructure, so they still carry the same

limitations as the SqlMembership Provider. That is, they were designed for relational databases and it's hard to customize profile and user information. These providers also still use Forms Authentication for sign-in and sign-out functionality.

ASP.NET Identity

As the membership story in ASP.NET has evolved over the years, the ASP.NET team has learned a lot from feedback from customers.

The assumption that users will sign in by entering a user name and password that they have registered in your own application is no longer valid. The web has become more social. Users are interacting with each other in real time through social channels such as Facebook, Twitter, and other social web sites. Developers want users to be able to sign in with their social identities so that they can have a rich experience on their web sites. A modern membership system must enable redirection-based log-ins to authentication providers such as Facebook, Twitter, and others.

As web development evolved, so did the patterns of web development. Unit testing of application code became a core concern for application developers. In 2008 ASP.NET added a new framework based on the Model-View-Controller (MVC) pattern, in part to help developers build unit testable ASP.NET applications. Developers who wanted to unit test their application logic also wanted to be able to do that with the membership system.

Considering these changes in web application development, ASP.NET Identity was developed with the following goals:

- **One ASP.NET Identity system**
  - ASP.NET Identity can be used with all of the ASP.NET frameworks, such as ASP.NET MVC, Web Forms, Web Pages, Web API, and SignalR.
  - ASP.NET Identity can be used when you are building web, phone, store, or hybrid applications.
- **Ease of plugging in profile data about the user**
  - You have control over the schema of user and profile information. For example, you can easily enable the system to store birth dates entered by users when they register an account in your application.
- **Persistence control**
  - By default, the ASP.NET Identity system stores all the user information in a database. ASP.NET Identity uses Entity Framework Code First to implement all of its persistence mechanism.
  - Since you control the database schema, common tasks such as changing table names or changing the data type of primary keys is simple to do.
  - It's easy to plug in different storage mechanisms such as SharePoint, Azure Storage Table Service, NoSQL databases, etc., without having to throw `System.NotImplementedExceptions` exceptions.
- **Unit testability**
  - ASP.NET Identity makes the web application more unit testable. You can write unit tests for the parts of your application that use ASP.NET Identity.
- **Role provider**
  - There is a role provider which lets you restrict access to parts of your application by roles. You can easily create roles such as "Admin" and add users to roles.
- **Claims Based**
  - ASP.NET Identity supports claims-based authentication, where the user's identity is represented as a set of claims. Claims allow developers to be a lot more expressive in describing a user's identity than roles allow. Whereas role membership is just a boolean (member or non-member), a claim can include rich information about the user's identity and membership.

- **Social Login Providers**
  - You can easily add social log-ins such as Microsoft Account, Facebook, Twitter, Google, and others to your application, and store the user-specific data in your application.
- **OWIN Integration**
  - ASP.NET authentication is now based on OWIN middleware that can be used on any OWIN-based host. ASP.NET Identity does not have any dependency on System.Web. It is a fully compliant OWIN framework and can be used in any OWIN hosted application.
  - ASP.NET Identity uses OWIN Authentication for log-in/log-out of users in the web site. This means that instead of using FormsAuthentication to generate the cookie, the application uses OWIN CookieAuthentication to do that.
- **NuGet package**
  - ASP.NET Identity is redistributed as a NuGet package which is installed in the ASP.NET MVC, Web Forms and Web API templates that ship with Visual Studio 2017. You can download this NuGet package from the NuGet gallery.
  - Releasing ASP.NET Identity as a NuGet package makes it easier for the ASP.NET team to iterate on new features and bug fixes, and deliver these to developers in an agile manner.

Get started with ASP.NET Identity

ASP.NET Identity is used in the Visual Studio 2017 project templates for ASP.NET MVC, Web Forms, Web API and SPA. In this walkthrough, we'll illustrate how the project templates use ASP.NET Identity to add functionality to register, sign in and sign out a user.

ASP.NET Identity is implemented using the following procedure. The purpose of this article is to give you a high level overview of ASP.NET Identity; you can follow it step by step or just read the details. For more detailed instructions on creating apps using ASP.NET Identity, including using the new API to add users, roles and profile information, see the Next Steps section at the end of this article.

1. Create an ASP.NET MVC application with Individual Accounts. You can use ASP.NET Identity in ASP.NET MVC, Web Forms, Web API, SignalR etc. In this article we will start with an ASP.NET MVC application.

2. The created project contains the following three packages for ASP.NET Identity.

- `Microsoft.AspNet.Identity.EntityFramework`
  This package has the Entity Framework implementation of ASP.NET Identity which will persist the ASP.NET Identity data and schema to SQL Server.
- `Microsoft.AspNet.Identity.Core`
  This package has the core interfaces for ASP.NET Identity. This package can be used to write an implementation for ASP.NET Identity that targets different persistence stores such as Azure Table Storage, NoSQL databases etc.
- `Microsoft.AspNet.Identity.OWIN`
  This package contains functionality that is used to plug in OWIN authentication with ASP.NET Identity in ASP.NET applications. This is used when you add sign in functionality to your application and call into OWIN Cookie Authentication middleware to generate a cookie.

3. Creating a user.
   Launch the application and then click on the **Register** link to create a user. The following image shows the Register page that collects the user name and password.

When the user selects the **Register** button, the `Register` action of the Account controller creates the user by calling the ASP.NET Identity API, as highlighted below:

```
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Register(RegisterViewModel model)
{
    if (ModelState.IsValid)
    {
        var user = new ApplicationUser() { UserName = model.UserName };
        var result = await UserManager.CreateAsync(user, model.Password);
        if (result.Succeeded)
        {
            await SignInAsync(user, isPersistent: false);
            return RedirectToAction("Index", "Home");
        }
        else
        {
            AddErrors(result);
        }
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

4. Sign in.
   If the user was successfully created, she is signed in by the `SignInAsync` method.

```
 [HttpPost]
 [AllowAnonymous]
 [ValidateAntiForgeryToken]
public async Task<ActionResult> Register(RegisterViewModel model)
{
    if (ModelState.IsValid)
    {
        var user = new ApplicationUser { UserName = model.Email, Email = model.Email };
        var result = await UserManager.CreateAsync(user, model.Password);
        if (result.Succeeded)
        {
             await SignInManager.SignInAsync(user, isPersistent:false, rememberBrowser:false);

             // For more information on how to enable account confirmation and password reset please
visit https://go.microsoft.com/fwlink/?LinkID=320771
             // Send an email with this link
             // string code = await UserManager.GenerateEmailConfirmationTokenAsync(user.Id);
             // var callbackUrl = Url.Action("ConfirmEmail", "Account", new { userId = user.Id, code =
code }, protocol: Request.Url.Scheme);
             // await UserManager.SendEmailAsync(user.Id, "Confirm your account", "Please confirm your
account by clicking <a href=\"" + callbackUrl + "\">here</a>");

             return RedirectToAction("Index", "Home");
         }
         AddErrors(result);
     }

    // If we got this far, something failed, redisplay form
     return View(model);
 }
```

The `SignInManager.SignInAsync` method generates a ClaimsIdentity. Since ASP.NET Identity and OWIN Cookie Authentication are claims-based system, the framework requires the app to generate a ClaimsIdentity for the user. ClaimsIdentity has information about all the claims for the user, such as what roles the user belongs to.

5. Log off.
   Select the **Log off** link to call the LogOff action in the account controller.

```
// POST: /Account/LogOff
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult LogOff()
{
    AuthenticationManager.SignOut();
    return RedirectToAction("Index", "Home");
}
```

   The highlighted code above shows the OWIN `AuthenticationManager.SignOut` method. This is analogous to FormsAuthentication.SignOut method used by the FormsAuthentication module in Web Forms.

Components of ASP.NET Identity

The diagram below shows the components of the ASP.NET Identity system (select on this or on the diagram to enlarge it). The packages in green make up the ASP.NET Identity system. All the other packages are dependencies which are needed to use the ASP.NET Identity system in ASP.NET applications.

The following is a brief description of the NuGet packages not mentioned previously:

- Microsoft.Owin.Security.Cookies
  Middleware that enables an application to use cookie based authentication, similar to ASP.NET's Forms Authentication.
- EntityFramework
  Entity Framework is Microsoft's recommended data access technology for relational databases.

Migrating from Membership to ASP.NET Identity

We hope to soon provide guidance on migrating your existing apps that use ASP.NET Membership or Simple Membership to the new ASP.NET Identity system.

Next Steps

- Create an ASP.NET MVC 5 App with Facebook and Google OAuth2 and OpenID Sign-on
  The tutorial uses the ASP.NET Identity API to add profile information to the user database, and how to authenticate with Google and Facebook.
- Create an ASP.NET MVC app with auth and SQL DB and deploy to Azure App Service
  This tutorial shows how to use the Identity API to add users and roles.
- https://github.com/rustd/AspnetIdentitySample
  Sample application that shows how to add basic roles and user support and how to do roles and user

management.

ASP.NET Identity Recommended Resources

2/20/2020 • 7 minutes to read • Edit Online

by Rick Anderson

> This topic provides links to documentation resources about how to use ASP.NET Identity.
>
> If you know a great blog post, stackoverflow thread, or any other link that would be useful, [send us an email](aspnetue@microsoft.com?subject=Identity recommended resources) with the link or just leave a message at the bottom of this page.

Q&A (question/answer)

- Q: Locked out users who have enabled "remember me" (so they don't have to go through 2FA on that computer/browser) are not locked out. Why and how do I prevent that? Answer here.
- **Q**: How can I store custom claims, such as the user's real name, in the ASP.NET Identity cookie to avoid unnecessary database queries on every request. Answer here.
- **Q: Updating AspNetUser Password Hash**: I have 2 projects. One of them is using ASP.NET authentication, the other uses Windows authentication, which is the administration side. I want the Admin project to be able to manage the users of the other. I can modify everything except the password. Answer here.
- **Q**: How can I reset password as a admin for other users? Answer here.
- **Q**: Can I change the displayed name of the UserName field in ASP.NET MVC IdentityUser? Answer here.
- **Q**: How can I gran users permissions to add other users to certain roles? Answer here.
- **Q**: Storing profile information in the AspNetUsers table vs. the AspNetUserClaims table. Answer here.
- **Q**: Remember me when using an external authentication provider. Answer here.
- **Q**: Why does every request require a ApplicationDBContext, isn't that too much overhead?. Answer, No, the overhead is low.
- Q: How do I get a list of logged in users? Answer here.
- Q: How can I detect when a user logs in with Microsoft.AspNet.Identity? Answer here.
- Q: How do I get localized error messages for Identity? Answer here.
- Q: How do I configure the CookieMiddleware to get fresh claims every 30 minutes? Answer here.
- Q: How do modify the claims for the user after they have signed in? Answer here.
- Q: How do I invalidate security tokens? Answer here.
- Q: How do is store claims in the cookie middleware? Answer here.
- Q: I'd like to have a PIN or security check on each action method in my MVC app, but I'd like to store the users success so they don't have to enter the PIN on every request to that action method. Answer here.
- Q: I'd like to save the returned email address from a social provider to the DB, how do I do that? Answer here:
- Q: How can I detect when a user logs in both with/with-out a "remember me" cookie? Answer here.
- Q: Can I modify claims in ASP.NET Identity with OWIN after calling SignIn? Answer: Calling SignIn is exactly what you are supposed to do when you want to modify the claims for the user. It basically causes the ClaimsIdentity to be serialized into the cookie, which is why you see the new claims show up on subsequent requests.

Adding ASP.NET Identity to an Empty or Existing Web Forms Project

2/20/2020 • 10 minutes to read • Edit Online

This tutorial shows you how to add ASP.NET Identity (the new membership system for ASP.NET) to an ASP.NET application.

When you create a new Web Forms or MVC project in Visual Studio 2017 RTM with Individual Accounts, Visual Studio will install all the required packages and add all necessary classes for you. This tutorial will illustrate the steps to add ASP.NET Identity support to your existing Web Forms project or a new empty project. I will outline all the NuGet packages you need to install, and classes you need to add. I will go over sample Web Forms for registering new users and logging in while highlighting all main entry point APIs for user management and authentication. This sample will use the ASP.NET Identity default implementation for SQL data storage which is built on Entity Framework. This tutorial, we will use LocalDB for the SQL database.

Get started with ASP.NET Identity

1. Start by installing and running Visual Studio 2017.

2. Select **New Project** from the Start page, or you can use the menu and select **File**, and then **New Project**.

3. In the left pane, expand **Visual C#**, then select **Web**, then **ASP.NET Web Application (.Net Framework)**. Name your project "WebFormsIdentity" and select **OK**.

4. In the **New ASP.NET Project** dialog, select the **Empty** template.

Notice the **Change Authentication** button is disabled and no authentication support is provided in this template. The Web Forms, MVC and Web API templates allow you to select the authentication approach.

Add Identity packages to your app

In Solution Explorer, right-click your project and select **Manage NuGet Packages**. Search for and install the **Microsoft.AspNet.Identity.EntityFramework** package.

Note that this package will install the dependency packages: **EntityFramework** and **Microsoft ASP.NET**

Identity Core.

Add a web form to register users

1. In **Solution Explorer**, right-click your project and select **Add**, and then **Web Form**.

2. In the **Specify Name for Item** dialog box, name the new web form **Register**, and then select **OK**

3. Replace the markup in the generated *Register.aspx* file with the code below. The code changes are highlighted.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Register.aspx.cs"
Inherits="WebFormsIdentity.Register" %>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title></title>
</head>
<body style="font-family: Arial, Helvetica, sans-serif; font-size: small">
    <form id="form1" runat="server">
    <div>
        <h4 style="font-size: medium">Register a new user</h4>
        <hr />
        <p>
            <asp:Literal runat="server" ID="StatusMessage" />
        </p>
        <div style="margin-bottom:10px">
            <asp:Label runat="server" AssociatedControlID="UserName">User name</asp:Label>
            <div>
                <asp:TextBox runat="server" ID="UserName" />
            </div>
        </div>
        <div style="margin-bottom:10px">
            <asp:Label runat="server" AssociatedControlID="Password">Password</asp:Label>
            <div>
                <asp:TextBox runat="server" ID="Password" TextMode="Password" />
            </div>
        </div>
        <div style="margin-bottom:10px">
            <asp:Label runat="server" AssociatedControlID="ConfirmPassword">Confirm
password</asp:Label>
            <div>
                <asp:TextBox runat="server" ID="ConfirmPassword" TextMode="Password" />
            </div>
        </div>
        <div>
            <div>
                <asp:Button runat="server" OnClick="CreateUser_Click" Text="Register" />
            </div>
        </div>
    </div>
    </form>
</body>
</html>
```

NOTE

This is just a simplified version of the *Register.aspx* file that is created when you create a new ASP.NET Web Forms project. The markup above adds form fields and a button to register a new user.

4. Open the *Register.aspx.cs* file and replace the contents of the file with the following code:

```
using Microsoft.AspNet.Identity;
using Microsoft.AspNet.Identity.EntityFramework;
using System;
using System.Linq;

namespace WebFormsIdentity
{
   public partial class Register : System.Web.UI.Page
   {
      protected void CreateUser_Click(object sender, EventArgs e)
      {
         // Default UserStore constructor uses the default connection string named: DefaultConnection
         var userStore = new UserStore<IdentityUser>();
         var manager = new UserManager<IdentityUser>(userStore);

         var user = new IdentityUser() { UserName = UserName.Text };
         IdentityResult result = manager.Create(user, Password.Text);

         if (result.Succeeded)
         {
            StatusMessage.Text = string.Format("User {0} was created successfully!", user.UserName);
         }
         else
         {
            StatusMessage.Text = result.Errors.FirstOrDefault();
         }
      }
   }
}
```

NOTE

1. The code above is a simplified version of the *Register.aspx.cs* file that is created when you create a new ASP.NET Web Forms project.
2. The *IdentityUser* class is the default EntityFramework implementation of the *IUser* interface. *IUser* interface is the minimal interface for a user on ASP.NET Identity Core.
3. The *UserStore* class is the default EntityFramework implementation of a user store. This class implements the ASP.NET Identity Core's minimal interfaces: *IUserStore*, *IUserLoginStore*, *IUserClaimStore* and *IUserRoleStore*.
4. The *UserManager* class exposes user related APIs which will automatically save changes to the *UserStore*.
5. The *IdentityResult* class represents the result of an identity operation.

5. In **Solution Explorer**, right-click your project and select **Add**, **Add ASP.NET Folder** and then **App_Data**.

6. Open the *Web.config* file and add a connection string entry for the database we will use to store user information. The database will be created at runtime by EntityFramework for the Identity entities. The connection string is similar to one created for you when you create a new Web Forms project. The highlighted code shows the markup you should add:

```
<?xml version="1.0" encoding="utf-8"?>
<!--

    <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFactory,
EntityFramework">
      <parameters>
        <parameter value="v11.0" />
      </parameters>
    </defaultConnectionFactory>
    <providers>
      <provider invariantName="System.Data.SqlClient"
type="System.Data.Entity.SqlServer.SqlProviderServices, EntityFramework.SqlServer" />
    </providers>
  </entityFramework>
</configuration>
```

NOTE

For Visual Studio 2015 or higher, replace `(localdb)\v11.0` with `(localdb)\MSSQLLocalDB` in your connection string.

7. Right click file *Register.aspx* in your project and select **Set as Start Page**. Press Ctrl + F5 to build and run the web application. Enter a new user name and password and then select **Register**.

> **NOTE**
>
> ASP.NET Identity has support for validation and in this sample you can verify the default behavior on User and Password validators that come from the Identity Core package. The default validator for User (`UserValidator`) has a property `AllowOnlyAlphanumericUserNames` that has default value set to `true`. The default validator for Password (`MinimumLengthValidator`) ensures that password has at least 6 characters. These validators are properties on `UserManager` that can be overridden if you want to have custom validation,

Verify the LocalDb Identity database and tables generated by Entity Framework

1. In the **View** menu, select **Server Explorer**.

2. Expand **DefaultConnection (WebFormsIdentity)**, expand **Tables**, right-click **AspNetUsers** and then select **Show Table Data**.

Configure the application for OWIN authentication

At this point we have only added support for creating users. Now, we are going to demonstrate how we can add authentication to login a user. ASP.NET Identity uses Microsoft OWIN Authentication middleware for forms authentication. The OWIN Cookie Authentication is a cookie and claims based authentication mechanism that can be used by any framework hosted on OWIN or IIS. With this model, the same authentication packages can be used across multiple frameworks including ASP.NET MVC and Web Forms. For more information on project Katana and how to run middleware in a host agnostic see Getting Started with the Katana Project.

Install authentication packages to your application

1. In Solution Explorer, right-click your project and select **Manage NuGet Packages**. Search for and install the ***Microsoft.AspNet.Identity.Owin*** package.

2. Search for and install the ***Microsoft.Owin.Host.SystemWeb*** package.

> **NOTE**
>
> The **Microsoft.Aspnet.Identity.Owin** package contains a set of OWIN extension classes to manage and configure OWIN authentication middleware to be consumed by ASP.NET Identity Core packages. The **Microsoft.Owin.Host.SystemWeb** package contains an OWIN server that enables OWIN-based applications to run on IIS using the ASP.NET request pipeline. For more information see OWIN Middleware in the IIS integrated pipeline.

Add OWIN startup and authentication configuration classes

1. In **Solution Explorer**, right-click your project, select **Add**, and then **Add New Item**. In the search text box dialog, type "*owin*". Name the class "*Startup*" and select **Add**.

2. In the Startup.cs file, add the highlighted code shown below to configure OWIN cookie authentication.

```
using Microsoft.AspNet.Identity;
using Microsoft.Owin;
using Microsoft.Owin.Security.Cookies;
using Owin;

[assembly: OwinStartup(typeof(WebFormsIdentity.Startup))]

namespace WebFormsIdentity
{
   public class Startup
   {
      public void Configuration(IAppBuilder app)
      {
         // For more information on how to configure your application, visit
https://go.microsoft.com/fwlink/?LinkID=316888
         app.UseCookieAuthentication(new CookieAuthenticationOptions
         {
            AuthenticationType = DefaultAuthenticationTypes.ApplicationCookie,
            LoginPath = new PathString("/Login")
         });
      }
   }
}
```

NOTE

This class contains the `OwinStartup` attribute for specifying the OWIN startup class. Every OWIN application has a startup class where you specify components for the application pipeline. See OWIN Startup Class Detection for more info on this model.

Add web forms for registering and signing in users

1. Open the *Register.aspx.cs* file and add the following code which signs in the user when registration succeeds.

```
using Microsoft.AspNet.Identity;
using Microsoft.AspNet.Identity.EntityFramework;
using Microsoft.Owin.Security;
using System;
using System.Linq;
using System.Web;

namespace WebFormsIdentity
{
   public partial class Register : System.Web.UI.Page
   {
      protected void CreateUser_Click(object sender, EventArgs e)
      {
         // Default UserStore constructor uses the default connection string named: DefaultConnection
         var userStore = new UserStore<IdentityUser>();
         var manager = new UserManager<IdentityUser>(userStore);
         var user = new IdentityUser() { UserName = UserName.Text };

         IdentityResult result = manager.Create(user, Password.Text);

         if (result.Succeeded)
         {
            var authenticationManager = HttpContext.Current.GetOwinContext().Authentication;
            var userIdentity = manager.CreateIdentity(user,
DefaultAuthenticationTypes.ApplicationCookie);
            authenticationManager.SignIn(new AuthenticationProperties() { }, userIdentity);
            Response.Redirect("~/Login.aspx");
         }
         else
         {
            StatusMessage.Text = result.Errors.FirstOrDefault();
         }
      }
   }
}
```

NOTE

- Since ASP.NET Identity and OWIN Cookie Authentication are claims based system, the framework requires the app developer to generate a ClaimsIdentity for the user. ClaimsIdentity has information about all the claims for the user such as what Roles the user belongs to. You can also add more claims for the user at this stage.
- You can sign in the user by using the AuthenticationManager from OWIN and calling `SignIn` and passing in the ClaimsIdentity as shown above. This code will sign in the user and generate a cookie as well. This call is analogous to FormAuthentication.SetAuthCookie used by the FormsAuthentication module.

2. In **Solution Explorer**, right-click your project, select **Add**, and then **Web Form**. Name the web form **Login**.

3. Replace the contents of the *Login.aspx* file with the following code:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Login.aspx.cs"
Inherits="WebFormsIdentity.Login" %>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
   <title></title>
</head>
<body style="font-family: Arial, Helvetica, sans-serif; font-size: small">
   <form id="form1" runat="server">
      <div>
         <h4 style="font-size: medium">Log In</h4>
         <hr />
         <asp:PlaceHolder runat="server" ID="LoginStatus" Visible="false">
            <p>
               <asp:Literal runat="server" ID="StatusText" />
            </p>
         </asp:PlaceHolder>
         <asp:PlaceHolder runat="server" ID="LoginForm" Visible="false">
            <div style="margin-bottom: 10px">
               <asp:Label runat="server" AssociatedControlID="UserName">User name</asp:Label>
               <div>
                  <asp:TextBox runat="server" ID="UserName" />
               </div>
            </div>
            <div style="margin-bottom: 10px">
               <asp:Label runat="server" AssociatedControlID="Password">Password</asp:Label>
               <div>
                  <asp:TextBox runat="server" ID="Password" TextMode="Password" />
               </div>
            </div>
            <div style="margin-bottom: 10px">
               <div>
                  <asp:Button runat="server" OnClick="SignIn" Text="Log in" />
               </div>
            </div>
         </asp:PlaceHolder>
         <asp:PlaceHolder runat="server" ID="LogoutButton" Visible="false">
            <div>
               <div>
                  <asp:Button runat="server" OnClick="SignOut" Text="Log out" />
               </div>
            </div>
         </asp:PlaceHolder>
      </div>
   </form>
</body>
</html>
```

4. Replace the contents of the *Login.aspx.cs* file with the following:

```
using Microsoft.AspNet.Identity;
using Microsoft.AspNet.Identity.EntityFramework;
using Microsoft.Owin.Security;
using System;
using System.Web;
using System.Web.UI.WebControls;

namespace WebFormsIdentity
{
   public partial class Login : System.Web.UI.Page
   {
      protected void Page_Load(object sender, EventArgs e)
      {
         if (!IsPostBack)
         {
            if (User.Identity.IsAuthenticated)
            {
               StatusText.Text = string.Format("Hello {0}!!", User.Identity.GetUserName());
               LoginStatus.Visible = true;
               LogoutButton.Visible = true;
            }
            else
            {
               LoginForm.Visible = true;
            }
         }
      }

      protected void SignIn(object sender, EventArgs e)
      {
         var userStore = new UserStore<IdentityUser>();
         var userManager = new UserManager<IdentityUser>(userStore);
         var user = userManager.Find(UserName.Text, Password.Text);

         if (user != null)
         {
            var authenticationManager = HttpContext.Current.GetOwinContext().Authentication;
            var userIdentity = userManager.CreateIdentity(user,
DefaultAuthenticationTypes.ApplicationCookie);

            authenticationManager.SignIn(new AuthenticationProperties() { IsPersistent = false },
userIdentity);
            Response.Redirect("~/Login.aspx");
         }
         else
         {
            StatusText.Text = "Invalid username or password.";
            LoginStatus.Visible = true;
         }
      }

      protected void SignOut(object sender, EventArgs e)
      {
         var authenticationManager = HttpContext.Current.GetOwinContext().Authentication;
         authenticationManager.SignOut();
         Response.Redirect("~/Login.aspx");
      }
   }
}
```

NOTE

- The `Page_Load` now checks for the status of current user and takes action based on its `Context.User.Identity.IsAuthenticated` status. **Display Logged in User Name** : The Microsoft ASP.NET Identity Framework has added extension methods on System.Security.Principal.IIdentity that allows you to get the `UserName` and `UserId` for the logged in User. These extension methods are defined in the `Microsoft.AspNet.Identity.Core` assembly. These extension methods are the replacement for HttpContext.User.Identity.Name .
- SignIn method: `This` method replaces the previous `CreateUser_Click` method in this sample and now signs in the user after successfully creating the user.
  The Microsoft OWIN Framework has added extension methods on `System.Web.HttpContext` that allows you to get a reference to an `IOwinContext`. These extension methods are defined in `Microsoft.Owin.Host.SystemWeb` assembly. The `OwinContext` class exposes an `IAuthenticationManager` property that represents the Authentication middleware functionality available on the current request. You can sign in the user by using the `AuthenticationManager` from OWIN and calling `SignIn` and passing in the `ClaimsIdentity` as shown above. Because ASP.NET Identity and OWIN Cookie Authentication are claims-based system, the framework requires the app to generate a `ClaimsIdentity` for the user. The `ClaimsIdentity` has information about all the claims for the user, such as what roles the user belongs to. You can also add more claims for the user at this stage This code will sign in the user and generate a cookie as well. This call is analogous to FormAuthentication.SetAuthCookie used by the FormsAuthentication module.
- `SignOut` method: Gets a reference to the `AuthenticationManager` from OWIN and calls `SignOut`. This is analogous to FormsAuthentication.SignOut method used by the FormsAuthentication module.

5. Press **Ctrl + F5** to build and run the web application. Enter a new user name and password and then select **Register**.

Note: At this point, the new user is created and logged in.

6. Select the **Log out** button. You are redirected to the Log in form.

7. Enter an invalid user name or password and select the **Log in** button. The `UserManager.Find` method will return null and the error message: " *Invalid user name or password* " will be displayed.

http://localhost:41969/Login.a

Developing ASP.NET Apps with Azure Active Directory

2/20/2020 • 9 minutes to read • Edit Online

by Rick Anderson

Microsoft ASP.NET tools for Azure Active Directory simplifies enabling authentication for web apps hosted on Azure. You can use Azure Authentication to authenticate Office 365 users from your organization, corporate accounts synced from your on-premise Active Directory or users created in your own custom Azure Active Directory domain. Enabling Windows Azure Authentication configures your application to authenticate users using a single Azure Active Directory tenant.

This tutorial will show you how to create an ASP.NET application that is configured for sign-on with Azure Active Directory (Azure AD). You will also learn how to call the Graph API to get information about the currently signed-in user and how to deploy the application to Azure.

Prerequisites

1. Visual Studio Express 2013 for Web or Visual Studio 2013.
2. Visual Studio 2013 Update 4 - Update 3 or higher is required.
3. An Azure account. Click here for a free trial if you do not already have an account.

Add a Global Administrator to your Active Directory

1. Sign in to the Azure Management Portal.
2. All Azure accounts contain a **Default Directory** -- click on it, then click the **Users** tab at the top of the page (see image below).
3. Click Add User.

4. Create a new user with the **Global Administrator** role. Click **Users** from the top menu, and then click the **Add User** button on the command bar.

5. In the **Add User** dialog, enter a name for the new user and then click the right arrow.

6. Enter the user name and set the role to **Global Administrator**. Global administrators require an alternate email address for password recovery purposes. After you're finished, click the right arrow.

7. On the next page of the dialog, click **Create**. A temporary password will be created for the new user and displayed in the dialog.

Save the password, you will be required to change the password after the first log in. The following image shows the new admin account. You must use the Azure Active Directory to log into your app, not the Microsoft account also shown on this page.

Create an ASP.NET Application

The following steps use Visual Studio Express 2013 for Web, and requires Visual Studio 2013 Update 3.

1. In Visual Studio, click **File** and then **New Project**. On the **New Project** dialog, select the Visual C# Web project from the left menu and click **OK**. You may also want to uncheck the **Add Application Insights to Project** if you don't want the functionality for your application.

2. In the **New ASP.NET Project** dialog, select **MVC**, and then click **Change Authentication**.

3. On the **Change Authentication** dialog, select **Organizational Accounts**. These options can be used to automatically register your application with Azure AD as well as automatically configure your application to integrate with Azure AD. You don't have to use the **Change Authentication** dialog to register and configure your application, but it makes it much easier. If you are using Visual Studio 2012 for example, you can still manually register the application in the Azure Management Portal and update its configuration to integrate with Azure AD. In the drop-down menus, select **Cloud - Single Organization** and **Single Sign On, Read directory data**. Enter the domain for your Azure AD directory, for example (in the images below) *aricka0yahoo.onmicrosoft.com*, and then click **OK**. You can get the domain name from the Domains tab for the Default Directory on the azure portal (see the next image down).

The following image shows the domain name from the Azure portal.

> **NOTE**
>
> You can optionally configure the Application ID URI that will be registered in Azure AD by clicking **More Options**. The App ID URI is the unique identifier for an application, which is registered in Azure AD and used by the application to identify itself when communicating with Azure AD. For more information about the App ID URI and other properties of registered applications, see this topic. By clicking the checkbox below the App ID URI field, you can also choose to overwrite an existing registration in Azure AD that uses the same App ID URI.

4. After clicking **OK**, a sign-in dialog will appear, and you'll need to sign in using a Global Administrator account (not the Microsoft account associated with your subscription). If you created a new Administrator account earlier, you'll be required to change the password and then sign in again using the new password.

5. After you've successfully authenticated, the **New ASP.NET Project** dialog will show your authentication choice (**Organizational**) and the directory where the new application will be registered

(*aricka0yahoo.onmicrosoft.com* in the image below). Below this information, select the checkbox labeled **Host in the cloud**. If this checkbox is selected, the project will be provisioned as an Azure web app and will be enabled for easy publishing later. Click **OK**.

6. The **Configure Azure Website** dialog will appear, using an auto-generated site name and region. Also note the account you're currently signed into in the dialog. You want to make sure that this account is the one that your Azure subscription is attached to, typically a Microsoft account.

> **NOTE**
>
> This project requires a database. You need to select one of your existing databases, or create a new one. A database is required because the project already uses a local database file to store a small amount of authentication configuration data. When you deploy the application to an Azure Website, this database isn't packaged with the deployment, so you need to choose one that's accessible in the cloud. Click **OK**.

7. The project will be created, and your authentication options and web app options will be automatically configured with the project. Once this process has completed, run the project locally by pressing **^F5**. You will be required to sign in using your organizational account. Provide the username and password for the account you created earlier and click **Sign in**.

8. After successful sign in, the ASP.NET site will show that you've authenticated by displaying the username in the top right corner of the page.

If you get the error: Value cannot be null or empty. Parameter name: linkText

see the debug section at the end of the tutorial.

Basics of the Graph API

The Graph API is the programmatic interface used to perform CRUD and other operations on objects in your Azure AD directory. If you select an Organizational Account option for authentication when creating a new project in Visual Studio 2013, your application will already be configured to call the Graph API. This section briefly shows you how the Graph API works.

1. In your running application, click on the name of the signed-in user at the top right of the page. This will

take you to the User Profile page, which is an action on the Home Controller. You'll notice that the table contains user information about the administrator account you created earlier. This information is stored in your directory, and the Graph API is called to retrieve this information when the page loads.

2. Go back to Visual Studio and expand the **Controllers** folder and then open the **HomeController.cs** file. You'll see a **UserProfile()** action that contains code to retrieve a token and then call the Graph API. This code is duplicated below:

```
[Authorize]
public async Task UserProfile()
{
    string tenantId = ClaimsPrincipal.Current.FindFirst(TenantIdClaimType).Value;

    // Get a token for calling the Azure Active Directory Graph
    AuthenticationContext authContext = new
AuthenticationContext(String.Format(CultureInfo.InvariantCulture, LoginUrl, tenantId));
    ClientCredential credential = new ClientCredential(AppPrincipalId, AppKey);
    AuthenticationResult assertionCredential = authContext.AcquireToken(GraphUrl, credential);
    string authHeader = assertionCredential.CreateAuthorizationHeader();
    string requestUrl = String.Format(
        CultureInfo.InvariantCulture,
        GraphUserUrl,
        HttpUtility.UrlEncode(tenantId),
        HttpUtility.UrlEncode(User.Identity.Name));

    HttpClient client = new HttpClient();
    HttpRequestMessage request = new HttpRequestMessage(HttpMethod.Get, requestUrl);
    request.Headers.TryAddWithoutValidation("Authorization", authHeader);
    HttpResponseMessage response = await client.SendAsync(request);
    string responseString = await response.Content.ReadAsStringAsync();
    UserProfile profile = JsonConvert.DeserializeObject<UserProfile>(responseString);

    return View(profile);
}
```

To call the Graph API, you first need to retrieve a token. When the token is retrieved, its string value must be appended in the Authorization header for all subsequent requests to the Graph API. Most of the code above

handles the details of authenticating to Azure AD to get a token, using the token to make a call to the Graph API, and then transforming the response so that it can be presented in the View.

The most relevant portion for discussion is the following highlighted line: `UserProfile profile = JsonConvert.DeserializeObject<UserProfile>(responseString);`. This line represents the name of the user, which has been deserialized from the JSON response and is presented in the View.

You can call the Graph API using HttpClient and handle the raw data yourself, but an easier way is to use the Graph Client Library which is available via NuGet. The Client Library handles the raw HTTP requests and the transformation of the returned data for you, and makes it much easier to work with the Graph API in a .NET environment. See the related Graph API code samples on GitHub.

Deploy the Application to Azure

The following steps will show you how to deploy the application to Azure. In the earlier steps, you connected your new project with a web app on Azure, so it's ready to be published in just a few steps.

1. In Visual Studio, right-click on the project and select **Publish**. The **Publish Web** dialog will appear with each setting already configured. Click on the **Next** button to go to the **Settings** page. You may be prompted to authenticate; make sure you authenticate using your Azure subscription account (typically a Microsoft account) and not the organizational account you created earlier.

2. Check the **Enable Organizational Authentication** option. In the **Domain** field, enter the domain for your directory. From the **Access Level** drop-down, select **Single Sign On, Read directory data**. You'll notice that the previous database you used is already populated in the **Databases** section. Click **Publish**.

3. Visual Studio will begin deploying your website, and then a new browser window will appear. You may be prompted to authenticate to your directory once again. Once you've authenticated, you'll be redirected to your newly published website on Azure.

Debugging the app

If you get the following error: Value cannot be null or empty. Parameter name: linkText

Replace the code in the *Views\Shared_LoginPartial.cshtml* file with the following:

```
@{
   var user = "Null User";
   if (!String.IsNullOrEmpty(User.Identity.Name))
   {
      user = User.Identity.Name;
   }

}

@if (Request.IsAuthenticated)
{
    <text>
         <ul class="nav navbar-nav navbar-right">
            <li>
                @*@Html.ActionLink(User.Identity.Name, "UserProfile", "Home", routeValues: null,
htmlAttributes: null)*@
               @Html.ActionLink(user, "UserProfile", "Home", routeValues: null, htmlAttributes: null)
            </li>
            <li>
                @Html.ActionLink("Sign out", "SignOut", "Account")
            </li>
        </ul>
    </text>
}
else
{
     <ul class="nav navbar-nav navbar-right">
        <li>@Html.ActionLink("Sign in", "Index", "Home", routeValues: null, htmlAttributes: new { id =
"loginLink" })</li>
    </ul>
}
```

After running the app, if the logged in user shows "Null User", sign out, and sign back in with the Active Directory account you created earlier.

An excellent tutorial to follow is Rick Rainey's Deep Dive: Azure Websites and Organizational Authentication using Azure AD.

ASP.NET Identity: Using MySQL Storage with an EntityFramework MySQL Provider (C#)

2/20/2020 • 7 minutes to read • Edit Online

by Maurycy Markowski, Raquel Soares De Almeida, Robert McMurray

> This tutorial shows you how to replace the default data storage mechanism for **ASP.NET Identity** with EntityFramework (SQL client provider) with a MySQL provider.

The following topics will be covered in this tutorial:

- Creating a MySQL database on Azure
- Creating an MVC application using Visual Studio 2013 MVC template
- Configuring EntityFramework to work with a MySQL database provider
- Running the application to verify the results

At the end of this tutorial, you will have an MVC application with the ASP.NET Identity store that is using a MySQL database that is hosted in Azure.

Creating a MySQL database instance on Azure

1. Log in to the Azure Portal.
2. Click **NEW** at the bottom of the page, and then select **STORE**:

3. In the **Choose and Add-on** wizard, select **ClearDB MySQL Database**, and then click the **Next** arrow at the bottom of the frame:

   [Click the following image to expand it.]

4. Keep the default **Free** plan, change the **NAME** to **IdentityMySQLDatabase**, select the region that is nearest to you, and then click the **Next** arrow at the bottom of the frame:

   [Click the following image to expand it.]

5. Click the **PURCHASE** checkmark to complete the database creation.

   [Click the following image to expand it.]

6. After your database has been created, you can manage it from the **ADD-ONS** tab in the management portal. To retrieve the connection information for your database, click **CONNECTION INFO** at the bottom of the page:

   [Click the following image to expand it.]

7. Copy the connection string by clicking on the copy button by the **CONNECTIONSTRING** field and save it; you will use this information later in this tutorial for your MVC application:

   [Click the following image to expand it.]

Creating an MVC application project

To complete the steps in this section of the tutorial, you will first need to install Visual Studio Express 2013 for Web or Visual Studio 2013. Once Visual Studio has been installed, use the following steps to create a new MVC application project:

1. Open Visual Studio 2103.
2. Click **New Project** from the **Start** page, or you can click the **File** menu and then **New Project**:

   [Click the following image to expand it.]

3. When the **New Project** dialog box is displayed, expand **Visual C#** in the list of templates, then click **Web**, and select **ASP.NET Web Application**. Name your project **IdentityMySQLDemo** and then click **OK**:

   [Click the following image to expand it.]

4. In the **New ASP.NET Project** dialog, select the **MVC** templatewith the default options; this will configure **Individual User Accounts** as the authentication method. Click **OK**:

[Click the following image to expand it.]

Configure EntityFramework to work with a MySQL database

Update the Entity Framework assembly for your project

The MVC application that was created from the Visual Studio 2013 template contains a reference to the EntityFramework 6.0.0 package, but there have been updates to that assembly since its release which contain significant performance improvements. In order to use these latest updates in your application, use the following steps.

1. Open your MVC project in Visual Studio.
2. Click **Tools**, then click **NuGet Package Manager**, and then click **Package Manager Console**:

   [Click the following image to expand it.]

3. The **Package Manager Console** will appear in the bottom section of Visual Studio. Type "**Update-Package EntityFramework**" and press Enter:

   [Click the following image to expand it.]

Install the MySQL provider for EntityFramework

In order for EntityFramework to connect to MySQL database, you need to install a MySQL provider. To do so, open the **Package Manager Console** and type "**Install-Package MySql.Data.Entity -Pre**", and then press Enter.

> **NOTE**
>
> This is a pre-release version of the assembly, and as such it may contain bugs. You should not use a pre-release version of the provider in production.

[Click the following image to expand it.]

Making project configuration changes to the Web.config file for your application

In this section you will configure the Entity Framework to use the MySQL provider that you just installed, register the MySQL provider factory, and add your connection string from Azure.

> **NOTE**
>
> The following examples contain a specific assembly version for MySql.Data.dll. If the assembly version changes, you will need to modify the appropriate configuration settings with the correct version.

1. Open the Web.config file for your project in Visual Studio 2013.

2. Locate the following configuration settings, which define the default database provider and factory for the Entity Framework:

```
<entityFramework>
  <defaultConnectionFactory
      type="System.Data.Entity.Infrastructure.LocalDbConnectionFactory, EntityFramework">
    <parameters>
      <parameter value="v11.0" />
    </parameters>
  </defaultConnectionFactory>
  <providers>
    <provider
      invariantName="System.Data.SqlClient"
      type="System.Data.Entity.SqlServer.SqlProviderServices, EntityFramework.SqlServer" />
  </providers>
</entityFramework>
```

3. Replace those configuration settings with the following, which will configure the Entity Framework to use the MySQL provider:

```
<entityFramework>
  <providers>
    <provider invariantName="MySql.Data.MySqlClient"
      type="MySql.Data.MySqlClient.MySqlProviderServices, MySql.Data.Entity"/>
  </providers>
</entityFramework>
<system.data>
  <DbProviderFactories>
    <remove invariant="MySql.Data.MySqlClient"></remove>
    <add name="MySQL Data Provider"
      invariant="MySql.Data.MySqlClient"
      description=".Net Framework Data Provider for MySQL"
      type="MySql.Data.MySqlClient.MySqlClientFactory, MySql.Data, Version=6.7.2.0"/>
  </DbProviderFactories>
</system.data>
```

4. Locate the <connectionStrings> section and replace it with the following code, which will define the connection string for your MySQL database that is hosted on Azure (note that providerName value has also been changed from the original):

```
<connectionStrings>
  <add name="DefaultConnection"
    providerName="MySql.Data.MySqlClient"
    connectionString="[Insert your ConnectionString from Azure here]"/>
</connectionStrings>
```

Adding custom MigrationHistory context

Entity Framework Code First uses a **MigrationHistory** table to keep track of model changes and to ensure the consistency between the database schema and conceptual schema. However, this table does not work for MySQL by default because the primary key is too large. To remedy this situation, you will need to shrink the key size for that table. To do so, use the following steps:

1. The schema information for this table is captured in a **HistoryContext**, which can be modified as any other **DbContext**. To do so, add a new class file named **MySqlHistoryContext.cs** to the project, and replace its contents with the following code:

```
using System.Data.Common;
using System.Data.Entity;
using System.Data.Entity.Migrations.History;

namespace IdentityMySQLDemo
{
  public class MySqlHistoryContext : HistoryContext
  {
    public MySqlHistoryContext(
      DbConnection existingConnection,
      string defaultSchema)
    : base(existingConnection, defaultSchema)
    {
    }

    protected override void OnModelCreating(DbModelBuilder modelBuilder)
    {
      base.OnModelCreating(modelBuilder);
      modelBuilder.Entity<HistoryRow>().Property(h => h.MigrationId).HasMaxLength(100).IsRequired();
      modelBuilder.Entity<HistoryRow>().Property(h => h.ContextKey).HasMaxLength(200).IsRequired();
    }
  }
}
```

2. Next you will need to configure Entity Framework to use the modified **HistoryContext**, rather than default one. This can be done by leveraging code-based configuration features. To do so, add new class file named **MySqlConfiguration.cs** to your project and replace its contents with:

```
using System.Data.Entity;

namespace IdentityMySQLDemo
{
  public class MySqlConfiguration : DbConfiguration
  {
    public MySqlConfiguration()
    {
      SetHistoryContext(
      "MySql.Data.MySqlClient", (conn, schema) => new MySqlHistoryContext(conn, schema));
    }
  }
}
```

Creating a custom EntityFramework initializer for ApplicationDbContext

The MySQL provider that is featured in this tutorial does not currently support Entity Framework migrations, so you will need to use model initializers in order to connect to the database. Because this tutorial is using a MySQL instance on Azure, you will need to create a custom Entity Framework initializer.

> **NOTE**
> This step is not required if you are connecting to a SQL Server instance on Azure or if you are using a database that is hosted on premises.

To create a custom Entity Framework initializer for MySQL, use the following steps:

1. Add a new class file named **MySqlInitializer.cs** to the project, and replace it's contents with the following code:

```
using IdentityMySQLDemo.Models;
using System.Data.Entity;
using System.Data.Entity.Infrastructure;
using System.Linq;

namespace IdentityMySQLDemo
{
  public class MySqlInitializer : IDatabaseInitializer<ApplicationDbContext>
  {
    public void InitializeDatabase(ApplicationDbContext context)
    {
      if (!context.Database.Exists())
      {
        // if database did not exist before - create it
        context.Database.Create();
      }
      else
      {
        // query to check if MigrationHistory table is present in the database
        var migrationHistoryTableExists =
((IObjectContextAdapter)context).ObjectContext.ExecuteStoreQuery<int>(
          "SELECT COUNT(*) FROM information_schema.tables WHERE table_schema = 'IdentityMySQLDatabase'
AND table_name = '__MigrationHistory'");

        // if MigrationHistory table is not there (which is the case first time we run) - create it
        if (migrationHistoryTableExists.FirstOrDefault() == 0)
        {
          context.Database.Delete();
          context.Database.Create();
        }
      }
    }
  }
}
```

2. Open the **IdentityModels.cs** file for your project, which is located in the **Models** directory, and replace it's contents with the following:

```
using Microsoft.AspNet.Identity.EntityFramework;
using System.Data.Entity;

namespace IdentityMySQLDemo.Models
{
  // You can add profile data for the user by adding more properties to your ApplicationUser
  // class, please visit https://go.microsoft.com/fwlink/?LinkID=317594 to learn more.
  public class ApplicationUser : IdentityUser
  {
  }

  public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
  {
    static ApplicationDbContext()
    {
      Database.SetInitializer(new MySqlInitializer());
    }

    public ApplicationDbContext()
      : base("DefaultConnection")
    {
    }
  }
}
```

Running the application and verifying the database

Once you have completed the steps in the preceding sections, you should test your database. To do so, use the following steps:

1. Press **Ctrl + F5** to build and run the web application.

2. Click the **Register** tab on the top of the page:

   [Click the following image to expand it.]

3. Enter a new user name and password, and then click **Register**:

   [Click the following image to expand it.]

4. At this point the ASP.NET Identity tables are created on the MySQL Database, and the user is registered and logged into the application:

   [Click the following image to expand it.]

Installing MySQL Workbench tool to verify the data

1. Install the **MySQL Workbench** tool from the MySQL downloads page
2. In the installation wizard: **Feature Selection** tab, select **MySQL Workbench** under **applications** section.
3. Launch the app and add a new connection using the connection string data from the Azure MySQL database you created at the begging of this tutorial.
4. After establishing the connection, inspect the **ASP.NET Identity** tables created on the **IdentityMySQLDatabase.**
5. You will see that all ASP.NET Identity required tables are created as shown in the image below:

   [Click the following image to expand it.]

6. Inspect the **aspnetusers** table for instance to check for the entries as you register new users.

[Click the following image to expand it.]

Best practices for deploying passwords and other sensitive data to ASP.NET and Azure App Service

2/20/2020 • 7 minutes to read • Edit Online

by Rick Anderson

> This tutorial shows how your code can securely store and access secure information. The most important point is you should never store passwords or other sensitive data in source code, and you shouldn't use production secrets in development and test mode.
>
> The sample code is a simple WebJob console app and a ASP.NET MVC app that needs access to a database connection string password, Twilio, Google and SendGrid secure keys.
>
> On premise settings and PHP is also mentioned.

- Working with passwords in the development environment
- Working with connection strings in the development environment
- WebJobs console apps
- Deploying secrets to Azure
- Notes for On-Premise and PHP
- Additional Resources

Working with passwords in the development environment

Tutorials frequently show sensitive data in source code, hopefully with a caveat that you should never store sensitive data in source code. For example, my ASP.NET MVC 5 app with SMS and email 2FA tutorial shows the following in the *web.config* file:

```
</connectionStrings>
   <appSettings>
      <add key="webpages:Version" value="3.0.0.0" />
      <!-- Markup removed for clarity. -->

      <!-- SendGrid-->
      <add key="mailAccount" value="account" />
      <add key="mailPassword" value="my password" />
      <!-- Twilio-->
      <add key="TwilioSid" value="My SID" />
      <add key="TwilioToken" value="My Token" />
      <add key="TwilioFromPhone" value="+12065551234" />

      <add key="GoogClientID" value="1234.apps.googleusercontent.com" />
      <add key="GoogClientSecret" value="My GCS" />
   </appSettings>
 <system.web>
```

The *web.config* file is source code, so these secrets should never be stored in that file. Fortunately, the `<appSettings>` element has a `file` attribute that allows you to specify an external file that contains sensitive app config settings. You can move all your secrets to an external file as long as the external file is not checked into your source tree. For example, in the following markup, the file *AppSettingsSecrets.config* contains all the app secrets:

```
</connectionStrings>
   <appSettings file="..\..\AppSettingsSecrets.config">
      <add key="webpages:Version" value="3.0.0.0" />
      <add key="webpages:Enabled" value="false" />
      <add key="ClientValidationEnabled" value="true" />
      <add key="UnobtrusiveJavaScriptEnabled" value="true" />
   </appSettings>
  <system.web>
```

The markup in the external file (*AppSettingsSecrets.config* in this sample), is the same markup found in the *web.config* file:

```
<appSettings>
   <!-- SendGrid-->
   <add key="mailAccount" value="My mail account." />
   <add key="mailPassword" value="My mail password." />
   <!-- Twilio-->
   <add key="TwilioSid" value="My Twilio SID." />
   <add key="TwilioToken" value="My Twilio Token." />
   <add key="TwilioFromPhone" value="+12065551234" />

   <add key="GoogClientID" value="1.apps.googleusercontent.com" />
   <add key="GoogClientSecret" value="My Google client secret." />
</appSettings>
```

The ASP.NET runtime merges the contents of the external file with the markup in <appSettings> element. The runtime ignores the file attribute if the specified file cannot be found.

WARNING

Security - Do not add your *secrets .config* file to your project or check it into source control. By default, Visual Studio sets the `Build Action` to `Content`, which means the file is deployed. For more information see Why don't all of the files in my project folder get deployed? Although you can use any extension for the *secrets .config* file, it's best to keep it *.config*, as config files are not served by IIS. Notice also that the *AppSettingsSecrets.config* file is two directory levels up from the *web.config* file, so it's completely out of the solution directory. By moving the file out of the solution directory, "git add *" won't add it to your repository.

Working with connection strings in the development environment

Visual Studio creates new ASP.NET projects that use LocalDB. LocalDB was created specifically for the development environment. It doesn't require a password, therefore you don't need to do anything to prevent secrets from being checked into your source code. Some development teams use the full versions of SQL Server (or other DBMS) that require a password.

You can use the `configSource` attribute to replace the entire `<connectionStrings>` markup. Unlike the `<appSettings>` `file` attribute that merges the markup, the `configSource` attribute replaces the markup. The following markup shows the `configSource` attribute in the *web.config* file:

```
<connectionStrings configSource="ConnectionStrings.config">
</connectionStrings>
```

NOTE

If you use the `configSource` attribute as shown above to move your connection strings to an external file, and have Visual Studio create a new web site, it won't be able to detect you are using a database, and you won't get the option of configuring the database when you publish to Azure from Visual Studio. If you are using the `configSource` attribute, you can use PowerShell to create and deploy your web site and database, or you can create the web site and the database in the portal before you publish. The New-AzureWebsitewithDB.ps1 script will create a new web site and database.

WARNING

Security - Unlike the *AppSettingsSecrets.config* file, the external connection strings file must be in the same directory as the root *web.config* file, so you'll have to take precautions to ensure you don't check it into your source repository.

NOTE

Security Warning on secrets file: A best practice is to not use production secrets in test and development. Using production passwords in test or development leaks those secrets.

WebJobs console apps

The *app.config* file used by a console app doesn't support relative paths, but it does support absolute paths. You can use an absolute path to move your secrets out of your project directory. The following markup shows the secrets in the *C:\secrets\AppSettingsSecrets.config* file, and non sensitive data in the *app.config* file.

```
<configuration>
  <appSettings file="C:\secrets\AppSettingsSecrets.config">
    <add key="TwitterMaxThreads" value="24" />
    <add key="StackOverflowMaxThreads" value="24" />
    <add key="MaxDaysForPurge" value="30" />
  </appSettings>
</configuration>
```

Deploying secrets to Azure

When you deploy your web app to Azure, the *AppSettingsSecrets.config* file won't be deployed (that's what you want). You could go to the Azure Management Portal and set them manually, to do that:

1. Go to https://portal.azure.com, and sign in with your Azure credentials.
2. Click **Browse** > **Web Apps**, then click the name of your web app.
3. Click **All settings** > **Application settings**.

The **app settings** and **connection string** values override the same settings in the *web.config* file. In our example, we did not deploy these settings to Azure, but if these keys were in the *web.config* file, the settings shown on the portal would take precedence.

A best practice is to follow a DevOps workflow and use Azure PowerShell (or another framework such as Chef or Puppet) to automate setting these values in Azure. The following PowerShell script uses Export-CliXml to export the encrypted secrets to disk:

```
param(
  [Parameter(Mandatory=$true)]
  [String]$Name,
  [Parameter(Mandatory=$true)]
  [String]$Password)

$credPath = $PSScriptRoot + '\' + $Name + ".credential"
$PWord = ConvertTo-SecureString –String $Password –AsPlainText -Force
$Credential = New-Object –TypeName `
System.Management.Automation.PSCredential –ArgumentList $Name, $PWord
$Credential | Export-CliXml $credPath
```

In the script above, 'Name' is the name of the secret key, such as '"FB_AppSecret" or "TwitterSecret". You can view the ".credential" file created by the script in your browser. The snippet below tests each of the credential files and sets the secrets for the named web app:

```
Function GetPW_fromCredFile { Param( [String]$CredFile )
  $Credential = GetCredsFromFile $CredFile
  $PW = $Credential.GetNetworkCredential().Password
  # $user just for debugging.
  $user = $Credential.GetNetworkCredential().username
  Return $PW
}
$AppSettings = @{
  "FB_AppSecret"     = GetPW_fromCredFile "FB_AppSecret.credential";
  "GoogClientSecret" = GetPW_fromCredFile "GoogClientSecret.credential";
  "TwitterSecret"    = GetPW_fromCredFile "TwitterSecret.credential";
}
Set-AzureWebsite -Name $WebSiteName -AppSettings $AppSettings
```

WARNING

Security - Don't include passwords or other secrets in the PowerShell script, doing so defeats the purpose of using a PowerShell script to deploy sensitive data. The Get-Credential cmdlet provides a secure mechanism to obtain a password. Using a UI prompt can prevent leaking a password.

Deploying DB connection strings

DB connection strings are handled similarly to app settings. If you deploy your web app from Visual Studio, the connection string will be configured for you. You can verify this in the portal. The recommended way to set the connection string is with PowerShell. For an example of a PowerShell script the creates a website and database and sets the connection string in the website, download New-AzureWebsitewithDB.ps1 from the Azure Script library.

Notes for PHP

Since the key-value pairs for both **app settings** and **connection strings** are stored in environment variables on Azure App Service, developers that use any web app frameworks (such as PHP) can easily retrieve these values. See Stefan Schackow's Windows Azure Web Sites: How Application Strings and Connection Strings Work blog post which shows a PHP snippet to read app settings and connection strings.

Notes for on-premises servers

If you are deploying to on-premises web servers, you can help secure secrets by encrypting the configuration sections of configuration files. As an alternative, you can use the same approach recommended for Azure Websites: keep development settings in configuration files, and use environment variable values for production settings. In this case, however, you have to write application code for functionality that is automatic in Azure

Websites: retrieve settings from environment variables and use those values in place of configuration file settings, or use configuration file settings when environment variables are not found.

Additional Resources

For an example of a PowerShell script that creates a web app + database, sets the connection string + app settings, download New-AzureWebsitewithDB.ps1 from the Azure Script library.

See Stefan Schackow's Windows Azure Web Sites: How Application Strings and Connection Strings Work

Special thanks to Barry Dorrans (@blowdart) and Carlos Farre for reviewing.

Account confirmation and password recovery with ASP.NET Identity (C#)

2/20/2020 • 15 minutes to read • Edit Online

Before doing this tutorial you should first complete Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset. This tutorial contains more details and will show you how to set up email for local account confirmation and allow users to reset their forgotten password in ASP.NET Identity.

A local user account requires the user to create a password for the account, and that password is stored (securely) in the web app. ASP.NET Identity also supports social accounts, which don't require the user to create a password for the app. Social accounts use a third party (such as Google, Twitter, Facebook, or Microsoft) to authenticate users. This topic covers the following:

- Create an ASP.NET MVC app and explore ASP.NET Identity features.
- Build the Identity sample
- Set up email confirmation

New users register their email alias, which creates a local account.

Selecting the Register button sends a confirmation email containing a validation token to their email address.

The user is sent an email with a confirmation token for their account.

Selecting the link confirms the account.

Password recovery/reset

Local users who forget their password can have a security token sent to their email account, enabling them to reset their password.

The user will soon get an email with a link allowing them to reset their password.

Selecting the link will take them to the Reset page.

Selecting the **Reset** button will confirm the password has been reset.

Create an ASP.NET web app

Start by installing and running Visual Studio 2017.

1. Create a new ASP.NET Web project and select the MVC template. Web Forms also support ASP.NET Identity, so you could follow similar steps in a web forms app.

2. Change the authentication to **Individual User Accounts**.

3. Run the app, select the **Register** link and register a user. At this point, the only validation on the email is with the [EmailAddress] attribute.

4. In Server Explorer, navigate to **Data Connections\DefaultConnection\Tables\AspNetUsers**, right-click and select **Open table definition**.

   The following image shows the `AspNetUsers` schema:

5. Right-click on the **AspNetUsers** table and select **Show Table Data**.

   At this point the email has not been confirmed.

The default data store for ASP.NET Identity is Entity Framework, but you can configure it to use other data stores and to add additional fields. See Additional Resources section at the end of this tutorial.

The OWIN startup class (*Startup.cs*) is called when the app starts and invokes the `ConfigureAuth` method in *App_Start\Startup.Auth.cs*, which configures the OWIN pipeline and initializes ASP.NET Identity. Examine the `ConfigureAuth` method. Each `CreatePerOwinContext` call registers a callback (saved in the `OwinContext`) that will be called once per request to create an instance of the specified type. You can set a break point in the constructor and `Create` method of each type (`ApplicationDbContext, ApplicationUserManager`) and verify they are called on each request. A instance of `ApplicationDbContext` and `ApplicationUserManager` is stored in the OWIN context, which can be accessed throughout the application. ASP.NET Identity hooks into the OWIN pipeline through cookie middleware. For more information, see Per request lifetime management for UserManager class in ASP.NET Identity.

When you change your security profile, a new security stamp is generated and stored in the `SecurityStamp` field of the *AspNetUsers* table. Note, the `SecurityStamp` field is different from the security cookie. The security cookie is not stored in the `AspNetUsers` table (or anywhere else in the Identity DB). The security cookie token is self-signed using DPAPI and is created with the `UserId, SecurityStamp` and expiration time information.

The cookie middleware checks the cookie on each request. The `SecurityStampValidator` method in the `Startup` class hits the DB and checks security stamp periodically, as specified with the `validateInterval`. This only happens every 30 minutes (in our sample) unless you change your security profile. The 30 minute interval was chosen to minimize trips to the database. See my two-factor authentication tutorial for more details.

Per the comments in the code, the `UseCookieAuthentication` method supports cookie authentication. The `SecurityStamp` field and associated code provides an extra layer of security to your app, when you change your password, you will be logged out of the browser you logged in with. The `SecurityStampValidator.OnValidateIdentity` method enables the app to validate the security token when the user logs in, which is used when you change a password or use the external login. This is needed to ensure that any tokens (cookies) generated with the old password are invalidated. In the sample project, if you change the users password then a new token is generated for the user, any previous tokens are invalidated and the `SecurityStamp` field is updated.

The Identity system allow you to configure your app so when the users security profile changes (for example, when the user changes their password or changes associated login (such as from Facebook, Google, Microsoft account, etc.), the user is logged out of all browser instances. For example, the image below shows the Single signout sample app, which allows the user to sign out of all browser instances (in this case, IE, Firefox and Chrome) by selecting one button. Alternatively, the sample allows you to only log out of a specific browser instance.

The Single signout sample app shows how ASP.NET Identity allows you to regenerate the security token. This is needed to ensure that any tokens (cookies) generated with the old password are invalidated. This feature provides an extra layer of security to your application; when you change your password, you will be logged out where you have logged into this application.

The *App_Start\IdentityConfig.cs* file contains the `ApplicationUserManager`, `EmailService` and `SmsService` classes. The `EmailService` and `SmsService` classes each implement the `IIdentityMessageService` interface, so you have common methods in each class to configure email and SMS. Although this tutorial only shows how to add email notification through SendGrid, you can send email using SMTP and other mechanisms.

The `Startup` class also contains boiler plate to add social logins (Facebook, Twitter, etc.), see my tutorial MVC 5 App with Facebook, Twitter, LinkedIn and Google OAuth2 Sign-on for more info.

Examine the `ApplicationUserManager` class, which contains the users identity information and configures the following features:

- Password strength requirements.
- User lock out (attempts and time).
- Two-factor authentication (2FA). I'll cover 2FA and SMS in another tutorial.
- Hooking up the email and SMS services. (I'll cover SMS in another tutorial).

The `ApplicationUserManager` class derives from the generic `UserManager<ApplicationUser>` class. `ApplicationUser` derives from IdentityUser. `IdentityUser` derives from the generic `IdentityUser` class:

```
//     Default EntityFramework IUser implementation
public class IdentityUser<TKey, TLogin, TRole, TClaim> : IUser<TKey>
   where TLogin : IdentityUserLogin<TKey>
   where TRole : IdentityUserRole<TKey>
   where TClaim : IdentityUserClaim<TKey>
{
   public IdentityUser()
   {
      Claims = new List<TClaim>();
      Roles = new List<TRole>();
      Logins = new List<TLogin>();
   }

   ///     User ID (Primary Key)
   public virtual TKey Id { get; set; }

   public virtual string Email { get; set; }
   public virtual bool EmailConfirmed { get; set; }

   public virtual string PasswordHash { get; set; }

   ///     A random value that should change whenever a users credentials have changed (password changed,
login removed)
   public virtual string SecurityStamp { get; set; }

   public virtual string PhoneNumber { get; set; }
   public virtual bool PhoneNumberConfirmed { get; set; }

   public virtual bool TwoFactorEnabled { get; set; }

   ///     DateTime in UTC when lockout ends, any time in the past is considered not locked out.
   public virtual DateTime? LockoutEndDateUtc { get; set; }

   public virtual bool LockoutEnabled { get; set; }

   ///     Used to record failures for the purposes of lockout
   public virtual int AccessFailedCount { get; set; }

   ///     Navigation property for user roles
   public virtual ICollection<TRole> Roles { get; private set; }

   ///     Navigation property for user claims
   public virtual ICollection<TClaim> Claims { get; private set; }

   ///     Navigation property for user logins
   public virtual ICollection<TLogin> Logins { get; private set; }

   public virtual string UserName { get; set; }
}
```

The properties above coincide with the properties in the `AspNetUsers` table, shown above.

Generic arguments on `IUser` enable you to derive a class using different types for the primary key. See the ChangePK sample which shows how to change the primary key from string to int or GUID.

ApplicationUser

`ApplicationUser` (`public class ApplicationUserManager : UserManager<ApplicationUser>`) is defined in *Models\IdentityModels.cs* as:

```
public class ApplicationUser : IdentityUser
{
    public async Task<ClaimsIdentity> GenerateUserIdentityAsync(
        UserManager<ApplicationUser> manager)
    {
        // Note the authenticationType must match the one defined in
       //   CookieAuthenticationOptions.AuthenticationType
        var userIdentity = await manager.CreateIdentityAsync(this,
    DefaultAuthenticationTypes.ApplicationCookie);
        // Add custom user claims here
        return userIdentity;
    }
}
```

The highlighted code above generates a ClaimsIdentity. ASP.NET Identity and OWIN Cookie Authentication are claims-based, therefore the framework requires the app to generate a `ClaimsIdentity` for the user. `ClaimsIdentity` has information about all the claims for the user, such as the user's name, age and what roles the user belongs to. You can also add more claims for the user at this stage.

The OWIN `AuthenticationManager.SignIn` method passes in the `ClaimsIdentity` and signs in the user:

```
private async Task SignInAsync(ApplicationUser user, bool isPersistent)
{
    AuthenticationManager.SignOut(DefaultAuthenticationTypes.ExternalCookie);
    AuthenticationManager.SignIn(new AuthenticationProperties(){
       IsPersistent = isPersistent },
       await user.GenerateUserIdentityAsync(UserManager));
}
```

MVC 5 App with Facebook, Twitter, LinkedIn and Google OAuth2 Sign-on shows how you can add additional properties to the `ApplicationUser` class.

Email confirmation

It's a good idea to confirm the email a new user register with to verify they are not impersonating someone else (that is, they haven't registered with someone else's email). Suppose you had a discussion forum, you would want to prevent `"bob@example.com"` from registering as `"joe@contoso.com"`. Without email confirmation, `"joe@contoso.com"` could get unwanted email from your app. Suppose Bob accidentally registered as `"bib@example.com"` and hadn't noticed it, he wouldn't be able to use password recover because the app doesn't have his correct email. Email confirmation provides only limited protection from bots and doesn't provide protection from determined spammers, they have many working email aliases they can use to register.In the sample below, the user won't be able to change their password until their account has been confirmed (by them selecting a confirmation link received on the email account they registered with.) You can apply this work flow to other scenarios, for example sending a link to confirm and reset the password on new accounts created by the administrator, sending the user an email when they have changed their profile and so on. You generally want to prevent new users from posting any data to your web site before they have been confirmed by email, a SMS text message or another mechanism.

Build a more complete sample

In this section, you'll use NuGet to download a more complete sample we will work with.

1. Create a new ***empty*** ASP.NET Web project.

2. In the Package Manager Console, enter the following commands:

```
Install-Package SendGrid
Install-Package -Prerelease Microsoft.AspNet.Identity.Samples
```

In this tutorial, we'll use SendGrid to send email. The `Identity.Samples` package installs the code we will be working with.

3. Set the project to use SSL.
4. Test local account creation by running the app, selecting the **Register** link, and posting the registration form.
5. Select the demo email link, which simulates email confirmation.
6. Remove the demo email link confirmation code from the sample (The `ViewBag.Link` code in the account controller. See the `DisplayEmail` and `ForgotPasswordConfirmation` action methods and razor views).

> **WARNING**
> If you change any of the security settings in this sample, productions apps will need to undergo a security audit that explicitly calls the changes made.

Examine the code in App_Start\IdentityConfig.cs

The sample shows how to create an account and add it to the *Admin* role. You should replace the email in the sample with the email you will be using for the admin account. The easiest way right now to create an administrator account is programmatically in the `Seed` method. We hope to have a tool in the future that will allow you to create and administer users and roles. The sample code does let you create and manage users and roles, but you must first have an administrators account to run the roles and user admin pages. In this sample, the admin account is created when the DB is seeded.

Change the password and change the name to an account where you can receive email notifications.

> **WARNING**
> Security - Never store sensitive data in your source code.

As mentioned previously, the `app.CreatePerOwinContext` call in the startup class adds callbacks to the `Create` method of the app DB content, user manager and role manger classes. The OWIN pipeline calls the `Create` method on these classes for each request and stores the context for each class. The account controller exposes the user manager from the HTTP context (which contains the OWIN context):

```
public ApplicationUserManager UserManager
{
    get
    {
        return _userManager ??
    HttpContext.GetOwinContext().GetUserManager<ApplicationUserManager>();
    }
    private set
    {
        _userManager = value;
    }
}
```

When a user registers a local account, the `HTTP Post Register` method is called:

```
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Register(RegisterViewModel model)
{
    if (ModelState.IsValid)
    {
        var user = new ApplicationUser { UserName = model.Email, Email = model.Email };
        var result = await UserManager.CreateAsync(user, model.Password);
        if (result.Succeeded)
        {
            var code = await UserManager.GenerateEmailConfirmationTokenAsync(user.Id);
            var callbackUrl = Url.Action(
               "ConfirmEmail", "Account",
               new { userId = user.Id, code = code },
               protocol: Request.Url.Scheme);

            await UserManager.SendEmailAsync(user.Id,
               "Confirm your account",
               "Please confirm your account by clicking this link: <a href=\""
                                                + callbackUrl + "\">link</a>");
            // ViewBag.Link = callbackUrl;   // Used only for initial demo.
            return View("DisplayEmail");
        }
        AddErrors(result);
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

The code above uses the model data to create a new user account using the email and password entered. If the email alias is in the data store, account creation fails and the form is displayed again. The `GenerateEmailConfirmationTokenAsync` method creates a secure confirmation token and stores it in the ASP.NET Identity data store. The Url.Action method creates a link containing the `UserId` and confirmation token. This link is then emailed to the user, the user can select on the link in their email app to confirm their account.

Set up email confirmation

Go to the Azure SendGrid sign up page and register for free account. Add code similar to the following to configure SendGrid:

```
public class EmailService : IIdentityMessageService
{
   public Task SendAsync(IdentityMessage message)
   {
      return configSendGridasync(message);
   }

   private Task configSendGridasync(IdentityMessage message)
   {
      var myMessage = new SendGridMessage();
      myMessage.AddTo(message.Destination);
      myMessage.From = new System.Net.Mail.MailAddress(
                          "Joe@contoso.com", "Joe S.");
      myMessage.Subject = message.Subject;
      myMessage.Text = message.Body;
      myMessage.Html = message.Body;

      var credentials = new NetworkCredential(
                 ConfigurationManager.AppSettings["mailAccount"],
                 ConfigurationManager.AppSettings["mailPassword"]
                 );

      // Create a Web transport for sending email.
      var transportWeb = new Web(credentials);

      // Send the email.
      if (transportWeb != null)
      {
         return transportWeb.DeliverAsync(myMessage);
      }
      else
      {
         return Task.FromResult(0);
      }
   }
}
```

NOTE

Email clients frequently accept only text messages (no HTML). You should provide the message in text and HTML. In the SendGrid sample above, this is done with the `myMessage.Text` and `myMessage.Html` code shown above.

The following code shows how to send email using the MailMessage class where `message.Body` returns only the link.

```
void sendMail(Message message)
{
#region formatter
   string text = string.Format("Please click on this link to {0}: {1}", message.Subject, message.Body);
   string html = "Please confirm your account by clicking this link: <a href=\"" + message.Body +
"\">link</a><br/>";

   html += HttpUtility.HtmlEncode(@"Or click on the copy the following link on the browser:" +
message.Body);
#endregion

   MailMessage msg = new MailMessage();
   msg.From = new MailAddress("joe@contoso.com");
   msg.To.Add(new MailAddress(message.Destination));
   msg.Subject = message.Subject;
   msg.AlternateViews.Add(AlternateView.CreateAlternateViewFromString(text, null,
MediaTypeNames.Text.Plain));
   msg.AlternateViews.Add(AlternateView.CreateAlternateViewFromString(html, null,
MediaTypeNames.Text.Html));

   SmtpClient smtpClient = new SmtpClient("smtp.gmail.com", Convert.ToInt32(587));
   System.Net.NetworkCredential credentials = new System.Net.NetworkCredential("joe@contoso.com",
"XXXXXX");
   smtpClient.Credentials = credentials;
   smtpClient.EnableSsl = true;
   smtpClient.Send(msg);
}
```

WARNING

Security - Never store sensitive data in your source code. The account and credentials are stored in the appSetting. On Azure, you can securely store these values on the **Configure** tab in the Azure portal. See Best practices for deploying passwords and other sensitive data to ASP.NET and Azure.

Enter your SendGrid credentials, run the app, register with an email alias can select the confirm link in your email. To see how to do this with your Outlook.com email account, see John Atten's C# SMTP Configuration for Outlook.Com SMTP Host and hisASP.NET Identity 2.0: Setting Up Account Validation and Two-Factor Authorization posts.

Once a user selects the **Register** button a confirmation email containing a validation token is sent to their email address.

The user is sent an email with a confirmation token for their account.

Examine the code

The following code shows the `POST ForgotPassword` method.

```
public async Task<ActionResult> ForgotPassword(ForgotPasswordViewModel model)
{
    if (ModelState.IsValid)
    {
        var user = await UserManager.FindByNameAsync(model.Email);
        if (user == null || !(await UserManager.IsEmailConfirmedAsync(user.Id)))
        {
            // Don't reveal that the user does not exist or is not confirmed
            return View("ForgotPasswordConfirmation");
        }

        var code = await UserManager.GeneratePasswordResetTokenAsync(user.Id);
        var callbackUrl = Url.Action("ResetPassword", "Account",
    new { UserId = user.Id, code = code }, protocol: Request.Url.Scheme);
        await UserManager.SendEmailAsync(user.Id, "Reset Password",
    "Please reset your password by clicking here: <a href=\"" + callbackUrl + "\">link</a>");
        return View("ForgotPasswordConfirmation");
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

The method fails silently if the user email has not been confirmed. If an error was posted for an invalid email address, malicious users could use that information to find valid userId (email aliases) to attack.

The following code shows the `ConfirmEmail` method in the account controller that is called when the user selects the confirmation link in the email sent to them:

```
public async Task<ActionResult> ConfirmEmail(string userId, string code)
{
    if (userId == null || code == null)
    {
        return View("Error");
    }
    var result = await UserManager.ConfirmEmailAsync(userId, code);
    if (result.Succeeded)
    {
        return View("ConfirmEmail");
    }
    AddErrors(result);
    return View();
}
```

Once a forgotten password token has been used, it's invalidated. The following code change in the `Create`

method (in the *App_Start\IdentityConfig.cs* file) sets the tokens to expire in 3 hours.

```
if (dataProtectionProvider != null)
 {
    manager.UserTokenProvider =
       new DataProtectorTokenProvider<ApplicationUser>
          (dataProtectionProvider.Create("ASP.NET Identity"))
          {
             TokenLifespan = TimeSpan.FromHours(3)
          };
 }
```

With the code above, the forgotten password and the email confirmation tokens will expire in 3 hours. The default `TokenLifespan` is one day.

The following code shows the email confirmation method:

```
// GET: /Account/ConfirmEmail
[AllowAnonymous]
public async Task<ActionResult> ConfirmEmail(string userId, string code)
{
   if (userId == null || code == null)
   {
      return View("Error");
   }
   IdentityResult result;
   try
   {
      result = await UserManager.ConfirmEmailAsync(userId, code);
   }
   catch (InvalidOperationException ioe)
   {
      // ConfirmEmailAsync throws when the userId is not found.
      ViewBag.errorMessage = ioe.Message;
      return View("Error");
   }

   if (result.Succeeded)
   {
      return View();
   }

   // If we got this far, something failed.
   AddErrors(result);
   ViewBag.errorMessage = "ConfirmEmail failed";
   return View("Error");
}
```

To make your app more secure, ASP.NET Identity supports Two-Factor authentication (2FA). See ASP.NET Identity 2.0: Setting Up Account Validation and Two-Factor Authorization by John Atten. Although you can set account lockout on login password attempt failures, that approach makes your login susceptible to DOS lockouts. We recommend you use account lockout only with 2FA.

Two-factor authentication using SMS and email with ASP.NET Identity

2/20/2020 • 17 minutes to read • Edit Online

by Hao Kung, Pranav Rastogi, Rick Anderson, Suhas Joshi

> This tutorial will show you how to set up Two-factor authentication (2FA) using SMS and email.
>
> This article was written by Rick Anderson (@RickAndMSFT), Pranav Rastogi (@rustd), Hao Kung, and Suhas Joshi. The NuGet sample was written primarily by Hao Kung.

This topic covers the following:

- Building the Identity sample
- Set up SMS for Two-factor authentication
- Enable Two-factor authentication
- How to register a Two-factor authentication provider
- Combine social and local login accounts
- Account lockout from brute force attacks

Building the Identity sample

In this section, you'll use NuGet to download a sample we will work with. Start by installing and running Visual Studio Express 2013 for Web or Visual Studio 2013. Install Visual Studio 2013 Update 2 or higher.

> **NOTE**
>
> Warning: You must install Visual Studio 2013 Update 2 to complete this tutorial.

1. Create a new ***empty*** ASP.NET Web project.

2. In the Package Manager Console, enter the following the following commands:

   ```
   Install-Package SendGrid
   Install-Package -Prerelease Microsoft.AspNet.Identity.Samples
   ```

   In this tutorial, we'll use SendGrid to send email and Twilio or ASPSMS for sms texting. The `Identity.Samples` package installs the code we will be working with.

3. Set the project to use SSL.

4. *Optional*: Follow the instructions in my Email confirmation tutorial to hook up SendGrid and then run the app and register an email account.

5. *Optional:* Remove the demo email link confirmation code from the sample (The `ViewBag.Link` code in the account controller. See the `DisplayEmail` and `ForgotPasswordConfirmation` action methods and razor views).

6. *Optional:* Remove the `ViewBag.Status` code from the Manage and Account controllers and from the *Views\Account\VerifyCode.cshtml* and *Views\Manage\VerifyPhoneNumber.cshtml* razor views. Alternatively, you can keep the `ViewBag.Status` display to test how this app works locally without having

to hook up and send email and SMS messages.

> **NOTE**
>
> Warning: If you change any of the security settings in this sample, productions apps will need to undergo a security audit that explicitly calls out the changes made.

Set up SMS for Two-factor authentication

This tutorial provides instructions for using either Twilio or ASPSMS but you can use any other SMS provider.

1. **Creating a User Account with an SMS provider**

   Create a Twilio or an ASPSMS account.

2. **Installing additional packages or adding service references**

   Twilio:
   In the Package Manager Console, enter the following command:
   `Install-Package Twilio`

   ASPSMS:
   The following service reference needs to be added:

   Address:
   `https://webservice.aspsms.com/aspsmsx2.asmx?WSDL`

   Namespace:
   `ASPSMSX2`

3. **Figuring out SMS Provider User credentials**

   Twilio:
   From the **Dashboard** tab of your Twilio account, copy the **Account SID** and **Auth token**.

ASPSMS:
From your account settings, navigate to **Userkey** and copy it together with your self-defined **Password**.

We will later store these values in the variables `SMSAccountIdentification` and `SMSAccountPassword` .

4. **Specifying SenderID / Originator**

   Twilio:
   From the **Numbers** tab, copy your Twilio phone number.

   ASPSMS:
   Within the **Unlock Originators** Menu, unlock one or more Originators or choose an alphanumeric Originator (Not supported by all networks).

   We will later store this value in the variable `SMSAccountFrom` .

5. **Transferring SMS provider credentials into app**

   Make the credentials and sender phone number available to the app:

```
public static class Keys
{
   public static string SMSAccountIdentification = "My Idenfitication";
   public static string SMSAccountPassword = "My Password";
   public static string SMSAccountFrom = "+15555551234";
}
```

> **WARNING**
> Security - Never store sensitive data in your source code. The account and credentials are added to the code above to keep the sample simple. See Jon Atten's ASP.NET MVC: Keep Private Settings Out of Source Control.

6. **Implementation of data transfer to SMS provider**

   Configure the `SmsService` class in the *App_Start\IdentityConfig.cs* file.

   Depending on the used SMS provider activate either the **Twilio** or the **ASPSMS** section:

```
public class SmsService : IIdentityMessageService
{
    public Task SendAsync(IdentityMessage message)
    {
        // Twilio Begin
        // var Twilio = new TwilioRestClient(
        //   Keys.SMSAccountIdentification,
        //   Keys.SMSAccountPassword);
        // var result = Twilio.SendMessage(
        //   Keys.SMSAccountFrom,
        //   message.Destination, message.Body
        // );
        // Status is one of Queued, Sending, Sent, Failed or null if the number is not valid
        // Trace.TraceInformation(result.Status);
        // Twilio doesn't currently have an async API, so return success.
        // return Task.FromResult(0);
        // Twilio End

        // ASPSMS Begin
        // var soapSms = new WebApplication1.ASPSMSX2.ASPSMSX2SoapClient("ASPSMSX2Soap");
        // soapSms.SendSimpleTextSMS(
        //   Keys.SMSAccountIdentification,
        //   Keys.SMSAccountPassword,
        //   message.Destination,
        //   Keys.SMSAccountFrom,
        //   message.Body);
        // soapSms.Close();
        // return Task.FromResult(0);
        // ASPSMS End
    }
}
```

7. Run the app and log in with the account you previously registered.
8. Click on your User ID, which activates the `Index` action method in `Manage` controller.

9. Click Add.

10. In a few seconds you will get a text message with the verification code. Enter it and press **Submit**.

11. The Manage view shows your phone number was added.

Examine the code

```
// GET: /Account/Index
public async Task<ActionResult> Index(ManageMessageId? message)
{
    ViewBag.StatusMessage =
        message == ManageMessageId.ChangePasswordSuccess ? "Your password has been changed."
        : message == ManageMessageId.SetPasswordSuccess ? "Your password has been set."
        : message == ManageMessageId.SetTwoFactorSuccess ? "Your two factor provider has been set."
        : message == ManageMessageId.Error ? "An error has occurred."
        : message == ManageMessageId.AddPhoneSuccess ? "The phone number was added."
        : message == ManageMessageId.RemovePhoneSuccess ? "Your phone number was removed."
        : "";

    var model = new IndexViewModel
    {
        HasPassword = HasPassword(),
        PhoneNumber = await UserManager.GetPhoneNumberAsync(User.Identity.GetUserId()),
        TwoFactor = await UserManager.GetTwoFactorEnabledAsync(User.Identity.GetUserId()),
        Logins = await UserManager.GetLoginsAsync(User.Identity.GetUserId()),
        BrowserRemembered = await
AuthenticationManager.TwoFactorBrowserRememberedAsync(User.Identity.GetUserId())
    };
    return View(model);
}
```

The `Index` action method in `Manage` controller sets the status message based on your previous action and provides links to change your local password or add a local account. The `Index` method also displays the state or your 2FA phone number, external logins, 2FA enabled, and remember 2FA method for this browser(explained later). Clicking on your user ID (email) in the title bar doesn't pass a message. Clicking on the **Phone Number : remove** link passes `Message=RemovePhoneSuccess` as a query string.

`https://localhost:44300/Manage?Message=RemovePhoneSuccess`

The `AddPhoneNumber` action method displays a dialog box to enter a phone number that can receive SMS messages.

```
// GET: /Account/AddPhoneNumber
public ActionResult AddPhoneNumber()
{
   return View();
}
```

Clicking on the **Send verification code** button posts the phone number to the HTTP POST `AddPhoneNumber` action method.

```
// POST: /Account/AddPhoneNumber
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> AddPhoneNumber(AddPhoneNumberViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }

    // Generate the token
    var code = await UserManager.GenerateChangePhoneNumberTokenAsync(
                                User.Identity.GetUserId(), model.Number);
    if (UserManager.SmsService != null)
    {
        var message = new IdentityMessage
        {
            Destination = model.Number,
            Body = "Your security code is: " + code
        };
        // Send token
        await UserManager.SmsService.SendAsync(message);
    }
    return RedirectToAction("VerifyPhoneNumber", new { PhoneNumber = model.Number });
}
```

The `GenerateChangePhoneNumberTokenAsync` method generates the security token which will be set in the SMS message. If the SMS service has been configured, the token is sent as the string "Your security code is <token>". The `SmsService.SendAsync` method to is called asynchronously, then the app is redirected to the `VerifyPhoneNumber` action method (which displays the following dialog), where you can enter the verification code.

Once you enter the code and click submit, the code is posted to the HTTP POST `VerifyPhoneNumber` action method.

```
// POST: /Account/VerifyPhoneNumber
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> VerifyPhoneNumber(VerifyPhoneNumberViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }
    var result = await UserManager.ChangePhoneNumberAsync(User.Identity.GetUserId(), model.PhoneNumber,
model.Code);
    if (result.Succeeded)
    {
        var user = await UserManager.FindByIdAsync(User.Identity.GetUserId());
        if (user != null)
        {
            await SignInAsync(user, isPersistent: false);
        }
        return RedirectToAction("Index", new { Message = ManageMessageId.AddPhoneSuccess });
    }
    // If we got this far, something failed, redisplay form
    ModelState.AddModelError("", "Failed to verify phone");
    return View(model);
}
```

The `ChangePhoneNumberAsync` method checks the posted security code. If the code is correct, the phone number is added to the `PhoneNumber` field of the `AspNetUsers` table. If that call is successful, the `SignInAsync` method is called:

```
private async Task SignInAsync(ApplicationUser user, bool isPersistent)
{
   // Clear the temporary cookies used for external and two factor sign ins
    AuthenticationManager.SignOut(DefaultAuthenticationTypes.ExternalCookie,
       DefaultAuthenticationTypes.TwoFactorCookie);
    AuthenticationManager.SignIn(new AuthenticationProperties
    {
       IsPersistent = isPersistent
    },
       await user.GenerateUserIdentityAsync(UserManager));
}
```

The `isPersistent` parameter sets whether the authentication session is persisted across multiple requests.

When you change your security profile, a new security stamp is generated and stored in the `SecurityStamp` field of the *AspNetUsers* table. Note, the `SecurityStamp` field is different from the security cookie. The security cookie is not stored in the `AspNetUsers` table (or anywhere else in the Identity DB). The security cookie token is self-signed using DPAPI and is created with the `UserId, SecurityStamp` and expiration time information.

The cookie middleware checks the cookie on each request. The `SecurityStampValidator` method in the `Startup` class hits the DB and checks security stamp periodically, as specified with the `validateInterval`. This only happens every 30 minutes (in our sample) unless you change your security profile. The 30 minute interval was chosen to minimize trips to the database.

The `SignInAsync` method needs to be called when any change is made to the security profile. When the security profile changes, the database is updates the `SecurityStamp` field, and without calling the `SignInAsync` method you would stay logged in *only* until the next time the OWIN pipeline hits the database (the `validateInterval`). You can test this by changing the `SignInAsync` method to return immediately, and setting the cookie `validateInterval` property from 30 minutes to 5 seconds:

```
private async Task SignInAsync(ApplicationUser user, bool isPersistent)
{
   return;

   // Clear any partial cookies from external or two factor partial sign ins
    AuthenticationManager.SignOut(DefaultAuthenticationTypes.ExternalCookie,
       DefaultAuthenticationTypes.TwoFactorCookie);
    AuthenticationManager.SignIn(new AuthenticationProperties
    {
       IsPersistent = isPersistent
    },
       await user.GenerateUserIdentityAsync(UserManager));
}
```

```
public void ConfigureAuth(IAppBuilder app) {
    // Configure the db context, user manager and role manager to use a single instance per request
    app.CreatePerOwinContext(ApplicationDbContext.Create);
    app.CreatePerOwinContext<ApplicationUserManager>(ApplicationUserManager.Create);
    app.CreatePerOwinContext<ApplicationRoleManager>(ApplicationRoleManager.Create);
    app.CreatePerOwinContext<ApplicationSignInManager>(ApplicationSignInManager.Create);

    // Enable the application to use a cookie to store information for the signed in user
    // and to use a cookie to temporarily store information about a user logging in with a
    // third party login provider
    // Configure the sign in cookie
    app.UseCookieAuthentication(new CookieAuthenticationOptions {
        AuthenticationType = DefaultAuthenticationTypes.ApplicationCookie,
        LoginPath = new PathString("/Account/Login"),
        Provider = new CookieAuthenticationProvider {
            // Enables the application to validate the security stamp when the user logs in.
            // This is a security feature which is used when you change a password or add
            // an external login to your account.
            OnValidateIdentity = SecurityStampValidator.OnValidateIdentity<ApplicationUserManager,
ApplicationUser>(
                //validateInterval: TimeSpan.FromMinutes(30),
                validateInterval: TimeSpan.FromSeconds(5),
                regenerateIdentity: (manager, user) => user.GenerateUserIdentityAsync(manager))
        }
    });
    app.UseExternalSignInCookie(DefaultAuthenticationTypes.ExternalCookie);
```

With the above code changes, you can change your security profile (for example, by changing the state of **Two Factor Enabled**) and you will be logged out in 5 seconds when the `SecurityStampValidator.OnValidateIdentity` method fails. Remove the return line in the `SignInAsync` method, make another security profile change and you will not be logged out. The `SignInAsync` method generates a new security cookie.

Enable two-factor authentication

In the sample app, you need to use the UI to enable two-factor authentication (2FA). To enable 2FA, click on your user ID (email alias) in the navigation bar.

Click on enable 2FA. Log out, then log back in. If you've enabled email (see my previous tutorial), you can select the SMS or email for 2FA.

The Verify Code page is displayed where you can enter the code (from SMS or email).

Clicking on the **Remember this browser** check box will exempt you from needing to use 2FA to log on with that computer and browser. Enabling 2FA and clicking on the **Remember this browser** will provide you with strong 2FA protection from malicious users trying to access your account, as long as they don't have access to your computer. You can do this on any private machine you regularly use. By setting **Remember this browser**, you get the added security of 2FA from computers you don't regularly use, and you get the convenience on not having to go through 2FA on your own computers.

How to register a Two-factor authentication provider

When you create a new MVC project, the *IdentityConfig.cs* file contains the following code to register a Two-factor authentication provider:

```
public static ApplicationUserManager Create(
   IdentityFactoryOptions<ApplicationUserManager> options,
   IOwinContext context)
{
    var manager = new ApplicationUserManager(
       new UserStore<ApplicationUser>(context.Get<ApplicationDbContext>()));
    // Configure validation logic for usernames
    manager.UserValidator = new UserValidator<ApplicationUser>(manager)
    {
        AllowOnlyAlphanumericUserNames = false,
        RequireUniqueEmail = true
    };
    // Configure validation logic for passwords
    manager.PasswordValidator = new PasswordValidator
    {
        RequiredLength = 6,
        RequireNonLetterOrDigit = true,
        RequireDigit = true,
        RequireLowercase = true,
        RequireUppercase = true,
    };
    // Register two factor authentication providers. This application uses Phone and Emails as a
    // step of receiving a code for verifying the user
    // You can write your own provider and plug it in here.
    manager.RegisterTwoFactorProvider("PhoneCode", new PhoneNumberTokenProvider<ApplicationUser>
    {
        MessageFormat = "Your security code is: {0}"
    });
    manager.RegisterTwoFactorProvider("EmailCode", new EmailTokenProvider<ApplicationUser>
    {
        Subject = "Security Code",
        BodyFormat = "Your security code is: {0}"
    });
    manager.EmailService = new EmailService();
    manager.SmsService = new SmsService();

    var dataProtectionProvider = options.DataProtectionProvider;
    if (dataProtectionProvider != null)
    {
        manager.UserTokenProvider = new DataProtectorTokenProvider<ApplicationUser>
           (dataProtectionProvider.Create("ASP.NET Identity"));
    }
    return manager;
}
```

Add a phone number for 2FA

The `AddPhoneNumber` action method in the `Manage` controller generates a security token and sends it to the phone number you have provided.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> AddPhoneNumber(AddPhoneNumberViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }
    // Generate the token and send it
    var code = await UserManager.GenerateChangePhoneNumberTokenAsync(
       User.Identity.GetUserId(), model.Number);
    if (UserManager.SmsService != null)
    {
        var message = new IdentityMessage
        {
            Destination = model.Number,
            Body = "Your security code is: " + code
        };
        await UserManager.SmsService.SendAsync(message);
    }
    return RedirectToAction("VerifyPhoneNumber", new { PhoneNumber = model.Number });
}
```

After sending the token, it redirects to the `VerifyPhoneNumber` action method, where you can enter the code to register SMS for 2FA. SMS 2FA is not used until you have verified the phone number.

Enabling 2FA

The `EnableTFA` action method enables 2FA:

```
// POST: /Manage/EnableTFA
[HttpPost]
public async Task<ActionResult> EnableTFA()
{
    await UserManager.SetTwoFactorEnabledAsync(User.Identity.GetUserId(), true);
    var user = await UserManager.FindByIdAsync(User.Identity.GetUserId());
    if (user != null)
    {
        await SignInAsync(user, isPersistent: false);
    }
    return RedirectToAction("Index", "Manage");
}
```

Note the `SignInAsync` must be called because enable 2FA is a change to the security profile. When 2FA is enabled, the user will need to use 2FA to log in, using the 2FA approaches they have registered (SMS and email in the sample).

You can add more 2FA providers such as QR code generators or you can write you own (See Using Google Authenticator with ASP.NET Identity).

> **NOTE**
>
> The 2FA codes are generated using Time-based One-time Password Algorithm and codes are valid for six minutes. If you take more than six minutes to enter the code, you'll get an Invalid code error message.

Combine social and local login accounts

You can combine local and social accounts by clicking on your email link. In the following sequence "RickAndMSFT@gmail.com" is first created as a local login, but you can create the account as a social log in

first, then add a local login.

Click on the **Manage** link. Note the 0 external (social logins) associated with this account.

Click the link to another log in service and accept the app requests. The two accounts have been combined, you will be able to log on with either account. You might want your users to add local accounts in case their social log in authentication service is down, or more likely they have lost access to their social account.

In the following image, Tom is a social log in (which you can see from the **External Logins: 1** shown on the

page).

Clicking on **Pick a password** allows you to add a local log on associated with the same account.

Account lockout from brute force attacks

You can protect the accounts on your app from dictionary attacks by enabling user lockout. The following code in the `ApplicationUserManager Create` method configures lock out:

```
// Configure user lockout defaults
manager.UserLockoutEnabledByDefault = true;
manager.DefaultAccountLockoutTimeSpan = TimeSpan.FromMinutes(5);
manager.MaxFailedAccessAttemptsBeforeLockout = 5;
```

The code above enables lockout for two factor authentication only. While you can enable lock out for logins by

changing `shouldLockout` to true in the `Login` method of the account controller, we recommend you not enable lock out for logins because it makes the account susceptible to DOS login attacks. In the sample code, lockout is disabled for the admin account created in the `ApplicationDbInitializer Seed` method:

```
public static void InitializeIdentityForEF(ApplicationDbContext db)
{
    var userManager = HttpContext.Current.GetOwinContext().GetUserManager<ApplicationUserManager>();
    var roleManager = HttpContext.Current.GetOwinContext().Get<ApplicationRoleManager>();
    const string name = "admin@example.com";
    const string roleName = "Admin";

    //Create Role Admin if it does not exist
    var role = roleManager.FindByName(roleName);
    if (role == null)
    {
        role = new IdentityRole(roleName);
        var roleresult = roleManager.Create(role);
    }

    var user = userManager.FindByName(name);
    if (user == null)
    {
        user = new ApplicationUser { UserName = name, Email = name };
        var result = userManager.Create(user, GetSecurePassword());
        result = userManager.SetLockoutEnabled(user.Id, false);
    }

    // Add user admin to Role Admin if not already added
    var rolesForUser = userManager.GetRoles(user.Id);
    if (!rolesForUser.Contains(role.Name))
    {
        var result = userManager.AddToRole(user.Id, role.Name);
    }
}
```

Requiring a user to have a validated email account

The following code requires a user to have a validated email account before they can log in:

```
public async Task<ActionResult> Login(LoginViewModel model, string returnUrl)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }

   // Require the user to have a confirmed email before they can log on.
    var user = await UserManager.FindByNameAsync(model.Email);
    if (user != null)
    {
       if (!await UserManager.IsEmailConfirmedAsync(user.Id))
       {
          ViewBag.errorMessage = "You must have a confirmed email to log on.";
          return View("Error");
       }
    }
    // This doen't count login failures towards lockout only two factor authentication
    // To enable password failures to trigger lockout, change to shouldLockout: true
    var result = await SignInManager.PasswordSignInAsync(model.Email, model.Password,
       model.RememberMe, shouldLockout: false);
    switch (result)
    {
        case SignInStatus.Success:
            return RedirectToLocal(returnUrl);
        case SignInStatus.LockedOut:
            return View("Lockout");
        case SignInStatus.RequiresVerification:
            return RedirectToAction("SendCode", new { ReturnUrl = returnUrl });
        case SignInStatus.Failure:
        default:
            ModelState.AddModelError("", "Invalid login attempt.");
            return View(model);
    }
}
```

How SignInManager checks for 2FA requirement

Both the local log in and social log in check to see if 2FA is enabled. If 2FA is enabled, the `SignInManager` logon method returns `SignInStatus.RequiresVerification`, and the user will be redirected to the `SendCode` action method, where they will have to enter the code to complete the log in sequence. If the user has RememberMe is set on the users local cookie, the `SignInManager` will return `SignInStatus.Success` and they will not have to go through 2FA.

```
public async Task<ActionResult> Login(LoginViewModel model, string returnUrl)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }

   // Require the user to have a confirmed email before they can log on.
    var user = await UserManager.FindByNameAsync(model.Email);
    if (user != null)
    {
       if (!await UserManager.IsEmailConfirmedAsync(user.Id))
       {
          ViewBag.errorMessage = "You must have a confirmed email to log on.";
          return View("Error");
       }
    }
    // This doen't count login failures towards lockout only two factor authentication
    // To enable password failures to trigger lockout, change to shouldLockout: true
    var result = await SignInManager.PasswordSignInAsync(model.Email, model.Password,
       model.RememberMe, shouldLockout: false);
    switch (result)
    {
        case SignInStatus.Success:
            return RedirectToLocal(returnUrl);
        case SignInStatus.LockedOut:
            return View("Lockout");
        case SignInStatus.RequiresVerification:
            return RedirectToAction("SendCode", new { ReturnUrl = returnUrl });
        case SignInStatus.Failure:
        default:
            ModelState.AddModelError("", "Invalid login attempt.");
            return View(model);
    }
}
```

```
public async Task<ActionResult> ExternalLoginCallback(string returnUrl)
{
    var loginInfo = await AuthenticationManager.GetExternalLoginInfoAsync();
    if (loginInfo == null)
    {
        return RedirectToAction("Login");
    }

    // Sign in the user with this external login provider if the user already has a login
    var result = await SignInManager.ExternalSignInAsync(loginInfo, isPersistent: false);
    switch (result)
    {
        case SignInStatus.Success:
            return RedirectToLocal(returnUrl);
        case SignInStatus.LockedOut:
            return View("Lockout");
        case SignInStatus.RequiresVerification:
            return RedirectToAction("SendCode", new { ReturnUrl = returnUrl });
        case SignInStatus.Failure:
        default:
            // If the user does not have an account, then prompt the user to create an account
            ViewBag.ReturnUrl = returnUrl;
            ViewBag.LoginProvider = loginInfo.Login.LoginProvider;
            return View("ExternalLoginConfirmation", new ExternalLoginConfirmationViewModel { Email =
loginInfo.Email });
    }
}
```

The following code shows the `SendCode` action method. A SelectListItem is created with all the 2FA methods

enabled for the user. The SelectListItem is passed to the DropDownListFor helper, which allows the user to select the 2FA approach (typically email and SMS).

```
public async Task<ActionResult> SendCode(string returnUrl)
{
    var userId = await SignInManager.GetVerifiedUserIdAsync();
    if (userId == null)
    {
        return View("Error");
    }
    var userFactors = await UserManager.GetValidTwoFactorProvidersAsync(userId);
    var factorOptions = userFactors.Select(purpose => new SelectListItem { Text = purpose, Value = purpose
}).ToList();
    return View(new SendCodeViewModel { Providers = factorOptions, ReturnUrl = returnUrl });
}
```

Once the user posts the 2FA approach, the `HTTP POST SendCode` action method is called, the `SignInManager` sends the 2FA code, and the user is redirected to the `VerifyCode` action method where they can enter the code to complete the log in.

```
//
// POST: /Account/SendCode
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> SendCode(SendCodeViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View();
    }

    // Generate the token and send it
    if (!await SignInManager.SendTwoFactorCodeAsync(model.SelectedProvider))
    {
        return View("Error");
    }
    return RedirectToAction("VerifyCode", new { Provider = model.SelectedProvider, ReturnUrl =
model.ReturnUrl });
}
```

2FA Lockout

Although you can set account lockout on login password attempt failures, that approach makes your login susceptible to DOS lockouts. We recommend you use account lockout only with 2FA. When the `ApplicationUserManager` is created, the sample code sets 2FA lockout and `MaxFailedAccessAttemptsBeforeLockout` to five. Once a user logs in (through local account or social account), each failed attempt at 2FA is stored, and if the maximum attempts is reached, the user is locked out for five minutes (you can set the lock out time with `DefaultAccountLockoutTimeSpan`).

Overview of Custom Storage Providers for ASP.NET Identity

2/20/2020 • 16 minutes to read • Edit Online

by Tom FitzMacken

ASP.NET Identity is an extensible system which enables you to create your own storage provider and plug it into your application without re-working the application. This topic describes how to create a customized storage provider for ASP.NET Identity. It covers the important concepts for creating your own storage provider, but it is not step-by-step walkthrough of implementing a custom storage provider.

For an example of implementing a custom storage provider, see Implementing a Custom MySQL ASP.NET Identity Storage Provider.

This topic was updated for ASP.NET Identity 2.0.

Software versions used in the tutorial

- Visual Studio 2013 with Update 2
- ASP.NET Identity 2

Introduction

By default, the ASP.NET Identity system stores user information in a SQL Server database, and uses Entity Framework Code First to create the database. For many applications, this approach works well. However, you may prefer to use a different type of persistence mechanism, such as Azure Table Storage, or you may already have database tables with a very different structure than the default implementation. In either case, you can write a customized provider for your storage mechanism and plug that provider into your application.

ASP.NET Identity is included by default in many of the Visual Studio 2013 templates. You can get updates to ASP.NET Identity through Microsoft AspNet Identity EntityFramework NuGet package.

This topic includes the following sections:

- Understand the architecture
- Understand the data that is stored
- Create the data access layer
- Customize the user class
- Customize the user store
- Customize the role class
- Customize the role store
- Reconfigure application to use new storage provider
- Other implementations of custom storage providers

Understand the architecture

ASP.NET Identity consists of classes called managers and stores. Managers are high-level classes which an application developer uses to perform operations, such as creating a user, in the ASP.NET Identity system. Stores are lower-level classes that specify how entities, such as users and roles, are persisted. Stores are closely coupled

with the persistence mechanism, but managers are decoupled from stores which means you can replace the persistence mechanism without disrupting the entire application.

The following diagram shows how your web application interacts with the managers, and stores interact with the data access layer.

To create a customized storage provider for ASP.NET Identity, you have to create the data source, the data access layer, and the store classes that interact with this data access layer. You can continue using the same manager APIs to perform data operations on the user but now that data is saved to a different storage system.

You do not need to customize the manager classes because when creating a new instance of UserManager or RoleManager you provide the type of the user class and pass an instance of the store class as an argument. This approach enables you to plug your customized classes into the existing structure. You will see how to instantiate UserManager and RoleManager with your customized store classes in the section Reconfigure application to use new storage provider.

Understand the data that is stored

To implement a custom storage provider, you must understand the types of data used with ASP.NET Identity, and decide which features are relevant to your application.

DATA	DESCRIPTION
Users	Registered users of your web site. Includes the user Id and user name. Might include a hashed password if users log in with credentials that are specific to your site (rather than using credentials from an external site like Facebook), and security stamp to indicate whether anything has changed in the user credentials. Might also include email address, phone number, whether two factor authentication is enabled, the current number of failed logins, and whether an account has been locked.
User Claims	A set of statements (or claims) about the user that represent the user's identity. Can enable greater expression of the user's identity than can be achieved through roles.
User Logins	Information about the external authentication provider (like Facebook) to use when logging in a user.

DATA	DESCRIPTION
Roles	Authorization groups for your site. Includes the role Id and role name (like "Admin" or "Employee").

Create the data access layer

This topic assumes you are familiar with the persistence mechanism that you are going to use and how to create entities for that mechanism. This topic does not provide details about how to create the repositories or data access classes; instead, it provides some suggestions about the design decisions you need to make when working with ASP.NET Identity.

You have a lot of freedom when designing the repositories for a customized store provider. You only need to create repositories for features that you intend to use in your application. For example, if you are not using roles in your application, you do not need to create storage for roles or user roles. Your technology and existing infrastructure may require a structure that is very different from the default implementation of ASP.NET Identity. In your data access layer, you provide the logic to work with the structure of your repositories.

For a MySQL implementation of data repositories for ASP.NET Identity 2.0, see MySQLIdentity.sql.

In the data access layer, you provide the logic to save the data from ASP.NET Identity to your data source. The data access layer for your customized storage provider might include the following classes to store user and role information.

CLASS	DESCRIPTION	EXAMPLE
Context	Encapsulates the information to connect to your persistence mechanism and execute queries. This class is central to your data access layer. The other data classes will require an instance of this class to perform their operations. You will also initialize your store classes with an instance of this class.	MySQLDatabase
User Storage	Stores and retrieves user information (such as user name and password hash).	UserTable (MySQL)
Role Storage	Stores and retrieves role information (such as the role name).	RoleTable (MySQL)
UserClaims Storage	Stores and retrieves user claim information (such as the claim type and value).	UserClaimsTable (MySQL)
UserLogins Storage	Stores and retrieves user login information (such as an external authentication provider).	UserLoginsTable (MySQL)
UserRole Storage	Stores and retrieves which roles a user is assigned to.	UserRoleTable (MySQL)

Again, you only need to implement the classes that you intend to use in your application.

In the data access classes, you provide code to perform data operations for your particular persistence

mechanism. For example, within the MySQL implementation, the UserTable class contains a method to insert a new record into the Users database table. The variable named `_database` is an instance of the MySQLDatabase class.

```
public int Insert(TUser user)
{
    string commandText = @"Insert into Users (UserName, Id, PasswordHash,
SecurityStamp,Email,EmailConfirmed,PhoneNumber,PhoneNumberConfirmed,
AccessFailedCount,LockoutEnabled,LockoutEndDateUtc,TwoFactorEnabled)
        values (@name, @id, @pwdHash,
@SecStamp,@email,@emailconfirmed,@phonenumber,@phonenumberconfirmed,@accesscount,@lockoutenabled,@lockoutendd
ate,@twofactorenabled)";
    Dictionary<string, object> parameters = new Dictionary<string, object>();
    parameters.Add("@name", user.UserName);
    parameters.Add("@id", user.Id);
    parameters.Add("@pwdHash", user.PasswordHash);
    parameters.Add("@SecStamp", user.SecurityStamp);
    parameters.Add("@email", user.Email);
    parameters.Add("@emailconfirmed", user.EmailConfirmed);
    parameters.Add("@phonenumber", user.PhoneNumber);
    parameters.Add("@phonenumberconfirmed", user.PhoneNumberConfirmed);
    parameters.Add("@accesscount", user.AccessFailedCount);
    parameters.Add("@lockoutenabled", user.LockoutEnabled);
    parameters.Add("@lockoutenddate", user.LockoutEndDateUtc);
    parameters.Add("@twofactorenabled", user.TwoFactorEnabled);

    return _database.Execute(commandText, parameters);
}
```

After creating your data access classes, you must create store classes that call the specific methods in the data access layer.

Customize the user class

When implementing your own storage provider, you must create a user class which is equivalent to the IdentityUser class in the Microsoft.ASP.NET.Identity.EntityFramework namespace:

The following diagram shows the IdentityUser class that you must create and the interface to implement in this class.

The IUser<TKey> interface defines the properties that the UserManager attempts to call when performing requested operations. The interface contains two properties - Id and UserName. The IUser<TKey> interface enables you to specify the type of the key for the user through the generic **TKey** parameter. The type of the Id property matches the value of the TKey parameter.

The Identity framework also provides the IUser interface (without the generic parameter) when you want to use a string value for the key.

The IdentityUser class implements IUser and contains any additional properties or constructors for users on your web site. The following example shows an IdentityUser class that uses an integer for the key. The Id field is set to **int** to match the value of the generic parameter.

```
public class IdentityUser : IUser<int>
{
    public IdentityUser() { ... }
    public IdentityUser(string userName) { ... }
    public int Id { get; set; }
    public string UserName { get; set; }
    // can also define optional properties such as:
    //    PasswordHash
    //    SecurityStamp
    //    Claims
    //    Logins
    //    Roles
}
```

For a complete implementation, see IdentityUser (MySQL).

Customize the user store

You also create a UserStore class that provides the methods for all data operations on the user. This class is equivalent to the UserStore<TUser> class in the Microsoft.ASP.NET.Identity.EntityFramework namespace. In your UserStore class, you implement the IUserStore<TUser, TKey> and any of the optional interfaces. You select which optional interfaces to implement based on the functionality you wish to provide in your application.

The following image shows the UserStore class you must create and the relevant interfaces.

The default project template in Visual Studio contains code that assumes many of the optional interfaces have been implemented in the user store. If you are using the default template with a customized user store, you must either implement optional interfaces in your user store or alter the template code to no longer call methods in the interfaces you have not implemented.

The following example shows a simple user store class. The **TUser** generic parameter takes the type of your user class which usually is the IdentityUser class you defined. The **TKey** generic parameter takes the type of your user key.

```
public class UserStore : IUserStore<IdentityUser, int>
{
    public UserStore() { ... }
    public UserStore(ExampleStorage database) { ... }
    public Task CreateAsync(IdentityUser user) { ... }
    public Task DeleteAsync(IdentityUser user) { ... }
    public Task<IdentityUser> FindByIdAsync(int userId) { ... }
    public Task<IdentityUser> FindByNameAsync(string userName) { ... }
    public Task UpdateAsync(IdentityUser user) { ... }
    public void Dispose() { ... }
}
```

In this example, the constructor that takes a parameter named *database* of type ExampleDatabase is only an illustration of how to pass in your data access class. For example, in the MySQL implementation, this constructor takes a parameter of type MySQLDatabase.

Within your UserStore class, you use the data access classes that you created to perform operations. For example, in the MySQL implementation, the UserStore class has the CreateAsync method which uses an instance of UserTable to insert a new record. The **Insert** method on the **userTable** object is the same method that was shown in the previous section.

```
public Task CreateAsync(IdentityUser user)
{
    if (user == null) {
        throw new ArgumentNullException("user");
    }

    userTable.Insert(user);

    return Task.FromResult<object>(null);
}
```

Interfaces to implement when customizing user store

The next image shows more details about the functionality defined in each interface. All of the optional interfaces inherit from IUserStore.

- **IUserStore**
  The IUserStore<TUser, TKey> interface is the only interface you must implement in your user store. It defines methods for creating, updating, deleting, and retrieving users.

- **IUserClaimStore**
  The IUserClaimStore<TUser, TKey> interface defines the methods you must implement in your user store to enable user claims. It contains methods or adding, removing and retrieving user claims.

- **IUserLoginStore**
  The IUserLoginStore<TUser, TKey> defines the methods you must implement in your user store to enable external authentication providers. It contains methods for adding, removing and retrieving user logins, and a method for retrieving a user based on the login information.

- **IUserRoleStore**
  The IUserRoleStore<TKey, TUser> interface defines the methods you must implement in your user store to map a user to a role. It contains methods to add, remove, and retrieve a user's roles, and a method to check if a user is assigned to a role.

- **IUserPasswordStore**
  The IUserPasswordStore<TUser, TKey> interface defines the methods you must implement in your user store to persist hashed passwords. It contains methods for getting and setting the hashed password, and a method that indicates whether the user has set a password.

- **IUserSecurityStampStore**
  The IUserSecurityStampStore<TUser, TKey> interface defines the methods you must implement in your user store to use a security stamp for indicating whether the user's account information has changed. This stamp is updated when a user changes the password, or adds or removes logins. It contains methods for getting and setting the security stamp.

- **IUserTwoFactorStore**
  The IUserTwoFactorStore<TUser, TKey> interface defines the methods you must implement to implement two factor authentication. It contains methods for getting and setting whether two factor authentication is enabled for a user.

- **IUserPhoneNumberStore**
  The IUserPhoneNumberStore<TUser, TKey> interface defines the methods you must implement to store user phone numbers. It contains methods for getting and setting the phone number and whether the phone number is confirmed.

- **IUserEmailStore**
  The IUserEmailStore<TUser, TKey> interface defines the methods you must implement to store user email addresses. It contains methods for getting and setting the email address and whether the email is confirmed.

- **IUserLockoutStore**
  The IUserLockoutStore<TUser, TKey> interface defines the methods you must implement to store information about locking an account. It contains methods for getting the current number of failed access attempts, getting and setting whether the account can be locked, getting and setting the lock out end date, incrementing the number of failed attempts, and resetting the number of failed attempts.

- **IQueryableUserStore**
  The IQueryableUserStore<TUser, TKey> interface defines the members you must implement to provide a queryable user store. It contains a property that holds the queryable users.

  You implement the interfaces that are needed in your application; such as, the IUserClaimStore, IUserLoginStore, IUserRoleStore, IUserPasswordStore, and IUserSecurityStampStore interfaces as shown below.

```
public class UserStore : IUserStore<IdentityUser, int>,
                         IUserClaimStore<IdentityUser, int>,
                         IUserLoginStore<IdentityUser, int>,
                         IUserRoleStore<IdentityUser, int>,
                         IUserPasswordStore<IdentityUser, int>,
                         IUserSecurityStampStore<IdentityUser, int>
{
    // interface implementations not shown
}
```

For a complete implementation (including all of interfaces), see UserStore (MySQL).

IdentityUserClaim, IdentityUserLogin, and IdentityUserRole

The Microsoft.AspNet.Identity.EntityFramework namespace contains implementations of the IdentityUserClaim, IdentityUserLogin, and IdentityUserRole classes. If you are using these features, you may want to create your own versions of these classes and define the properties for your application. However, sometimes it is more efficient to not load these entities into memory when performing basic operations (such as adding or removing a user's claim). Instead, the backend store classes can execute these operations directly on the data source. For example, the UserStore.GetClaimsAsync() method can call the userClaimTable.FindByUserId(user.Id) method to execute a query on that table directly and return a list of claims.

```
public Task<IList<Claim>> GetClaimsAsync(IdentityUser user)
{
    ClaimsIdentity identity = userClaimsTable.FindByUserId(user.Id);
    return Task.FromResult<IList<Claim>>(identity.Claims.ToList());
}
```

Customize the role class

When implementing your own storage provider, you must create a role class which is equivalent to the IdentityRole class in the Microsoft.ASP.NET.Identity.EntityFramework namespace:

The following diagram shows the IdentityRole class that you must create and the interface to implement in this class.

The IRole<TKey> interface defines the properties that the RoleManager attempts to call when performing requested operations. The interface contains two properties - Id and Name. The IRole<TKey> interface enables you to specify the type of the key for the role through the generic **TKey** parameter. The type of the Id property matches the value of the TKey parameter.

The Identity framework also provides the IRole interface (without the generic parameter) when you want to use a string value for the key.

The following example shows an IdentityRole class that uses an integer for the key. The Id field is set to int to match the value of the generic parameter.

```
public class IdentityRole : IRole<int>
{
    public IdentityRole() { ... }
    public IdentityRole(string roleName) { ... }
    public int Id { get; set; }
    public string Name { get; set; }
}
```

For a complete implementation, see IdentityRole (MySQL).

Customize the role store

You also create a RoleStore class that provides the methods for all data operations on roles. This class is equivalent to the RoleStore<TRole> class in the Microsoft.ASP.NET.Identity.EntityFramework namespace. In your RoleStore class, you implement the IRoleStore<TRole, TKey> and optionally the IQueryableRoleStore<TRole, TKey> interface.

The following example shows a role store class. The TRole generic parameter takes the type of your role class which usually is the IdentityRole class you defined. The TKey generic parameter takes the type of your role key.

```
public class RoleStore : IRoleStore<IdentityRole, int>
{
    public RoleStore() { ... }
    public RoleStore(ExampleStorage database) { ... }
    public Task CreateAsync(IdentityRole role) { ... }
    public Task DeleteAsync(IdentityRole role) { ... }
    public Task<IdentityRole> FindByIdAsync(int roleId) { ... }
    public Task<IdentityRole> FindByNameAsync(string roleName) { ... }
    public Task UpdateAsync(IdentityRole role) { ... }
    public void Dispose() { ... }
}
```

- **IRoleStore<TRole>**
  The IRoleStore interface defines the methods to implement in your role store class. It contains methods for creating, updating, deleting and retrieving roles.

- **RoleStore<TRole>**
  To customize RoleStore, create a class that implements the IRoleStore interface. You only have to implement this class if want to use roles on your system. The constructor that takes a parameter named *database* of type ExampleDatabase is only an illustration of how to pass in your data access class. For example, in the MySQL implementation, this constructor takes a parameter of type MySQLDatabase.

  For a complete implementation, see RoleStore (MySQL) .

Reconfigure application to use new storage provider

You have implemented your new storage provider. Now, you must configure your application to use this storage provider. If the default storage provider was included in your project, you must remove the default provider and replace it with your provider.

Replace default storage provider in MVC project

1. In the **Manage NuGet Packages** window, uninstall the **Microsoft ASP.NET Identity EntityFramework** package. You can find this package by searching in the Installed packages for Identity.EntityFramework.

   
   You will be asked if you also want to uninstall Entity Framework. If you do not need it in other parts of your application, you can uninstall it.

2. In the IdentityModels.cs file in the Models folder, delete or comment out the **ApplicationUser** and

ApplicationDbContext classes. In an MVC application, you can delete the entire IdentityModels.cs file. In a Web Forms application, delete the two classes but make sure you keep the helper class that is also located in the IdentityModels.cs file.

3. If your storage provider resides in a separate project, add a reference to it in your web application.

4. Replace all references to `using Microsoft.AspNet.Identity.EntityFramework;` with a using statement for the namespace of your storage provider.

5. In the **Startup.Auth.cs** class, change the **ConfigureAuth** method to use a single instance of the appropriate context.

```
public void ConfigureAuth(IAppBuilder app)
{
    app.CreatePerOwinContext(ExampleStorageContext.Create);
    app.CreatePerOwinContext(ApplicationUserManager.Create);
    ...
```

6. In the App_Start folder, open **IdentityConfig.cs**. In the ApplicationUserManager class, change the **Create** method to return a user manager that uses your customized user store.

```
public static ApplicationUserManager Create(IdentityFactoryOptions<ApplicationUserManager> options,
IOwinContext context)
{
    var manager = new ApplicationUserManager(new UserStore(context.Get<ExampleStorageContext>()));
    ...
}
```

7. Replace all references to **ApplicationUser** with **IdentityUser**.

8. The default project includes some members in user class which are not defined in the IUser interface; such as Email, PasswordHash, and GenerateUserIdentityAsync. If your user class does not have these members, you must either implement them or change the code that uses these members.

9. If you have created any instances of RoleManager, change that code to use your new RoleStore class.

```
var roleManager = new RoleManager<IdentityRole>(new RoleStore(context.Get<ExampleStorageContext>()));
```

10. The default project is designed for a user class that has a string value for the key. If your user class has a different type for the key (such as an integer), you must change the project to work with your type. See Change Primary Key for Users in ASP.NET Identity.

11. If needed, add the connection string to the Web.config file.

Implementing a Custom MySQL ASP.NET Identity Storage Provider

2/20/2020 • 6 minutes to read • Edit Online

by Raquel Soares De Almeida, Suhas Joshi, Tom FitzMacken

ASP.NET Identity is an extensible system which enables you to create your own storage provider and plug it into your application without re-working the application. This topic describes how to create a MySQL storage provider for ASP.NET Identity. For an overview of creating custom storage providers, see Overview of Custom Storage Providers for ASP.NET Identity.

To complete this tutorial, you must have Visual Studio 2013 with Update 2.

This tutorial will:

- Show how to create a MySQL database instance on Azure.
- Show how to use a MySQL client tool (MySQL Workbench) to create tables and manage your remote database on Azure.
- Show how to replace the default ASP.NET Identity storage implementation with our custom implementation on a MVC application project.

This tutorial was originally written by Raquel Soares De Almeida and Rick Anderson (@RickAndMSFT). The sample project was updated for Identity 2.0 by Suhas Joshi. The topic was updated for Identity 2.0 by Tom FitzMacken.

Download completed project

At the end of this tutorial, you will have an MVC application project with ASP.NET Identity working with a MySQL database hosted on Azure.

You can download the completed MySQL storage provider at AspNet.Identity.MySQL (GitHub).

The steps you will perform

In this tutorial you will:

1. Create a MySQL database on Azure
2. Create the ASP.NET Identity tables in MySQL
3. Create an MVC application and configure it to use the MySQL provider
4. Run the app

This topic does not cover the architecture of ASP.NET Identity and the decisions you must make when implementing a customer storage provider. For that information, see Overview of Custom Storage Providers for ASP.NET Identity.

Review MySQL storage provider classes

Before jumping into the steps to create the MySQL storage provider, let's look at the classes that make up the storage provider. You will need classes that manage the database operations and classes that are called from the application to manage users and roles.

Storage classes

- IdentityUser - contains properties for the user.
- UserStore - contains operations for adding, updating or retrieving users.
- IdentityRole - contains properties for roles.
- RoleStore - contains operations for adding, deleting, updating and retrieving roles.

Data access layer classes

For this example, the data access layer classes contain SQL statements for working with the tables; however, in your code you might want to use object-relational mapping (ORM) such as Entity Framework or NHibernate. In particular, your application may experience poor performance without an ORM that includes lazy loading and object caching. For more information, see ASP.NET Identity 2.0 without Entity Framework?

- MySQLDatabase - contains the MySQL database connection and methods for performing database operations. UserStore and RoleStore are both instantiated with an instance of this class.
- RoleTable - contains database operations for the table that stores roles.
- UserClaimsTable - contains database operations for the table that stores user claims.
- UserLoginsTable - contains database operations for the table that stores user login information.
- UserRoleTable - contains database operations for the table that stores which users are assigned to which roles.
- UserTable - contains database operations for the table that stores users.

Create a MySQL database instance on Azure

1. Log in to the Azure Portal.
2. Click **+NEW** at the bottom of the page, and then select **STORE**.

3. In the **Choose and Add-on** wizard, select **ClearDB MySQL Database** and click on the next arrow at the bottom right of the dialog.

4. Keep the default **Free** plan and change the **Name** to **IdentityMySQLDatabase**. Select the region nearest you

and then click the next arrow.

5. Click the checkmark to complete the database creation.

6. After your database has been created, you can manage it from the **ADD-ONS** tab in the management portal.

7. You can get the database connection information by clicking on **CONNECTION INFO** at the bottom of the page.

8. Copy the connection string by clicking on the copy button and save it so you can use later in your MVC application.

Create the ASP.NET Identity tables in a MySQL database

Install MySQL Workbench tool to connect and manage MySQL database

1. Install the **MySQL Workbench** tool from the MySQL downloads page
2. Launch the app and add click on the **MySQLConnections +** button to add a new connection. Use the connection string data you copied from the Azure MySQL database you created earlier in this tutorial.
3. After establishing the connection, open a new **Query** tab; paste the commands from MySQLIdentity.sql into the query and execute it in order to create the database tables.
4. You now have all the ASP.NET Identity necessary tables created on a MySQL database hosted on Azure as shown below.

Create an MVC application project from template and configure it to use MySQL provider

If needed, install either Visual Studio Express 2013 for Web or Visual Studio 2013 with Update 2.

Download the ASP.NET.Identity.MySQL project from GitHub

1. Browse to the repository URL at AspNet.Identity.MySQL (GitHub).
2. Download the source code.
3. Extract the .zip file into a local folder.
4. Open the AspNet.Identity.MySQL solution and build it.

Create a new MVC application project from template

1. Right click the **AspNet.Identity.MySQL** solution and **Add**, **New Project**
2. In the **Add New Project** Dialog select **Visual C#** on the left, then **Web** and then select **ASP.NET Web Application**. Name your project **IdentityMySQLDemo**; and then click OK.

3. In the **New ASP.NET Project** dialog, select the MVC template with the default options (that includes **Individual User Accounts** as authentication method) and click **OK**.

4. In Solution Explorer, right-click your IdentityMySQLDemo project and select **Manage NuGet Packages**. In the search text box dialog, type **Identity.EntityFramework**. Select this package in the list of results and click **Uninstall**. You will be prompted to uninstall the dependency package EntityFramework. Click on Yes as we will no longer this package on this application.

5. Right click the IdentityMySQLDemo project, select **Add**, **Reference, Solution, Projects;** select the AspNet.Identity.MySQL project and click **OK**.

6. In the IdentityMySQLDemo project, replace all references to

`using Microsoft.AspNet.Identity.EntityFramework;`

with

`using AspNet.Identity.MySQL;`

7. In IdentityModels.cs, set **ApplicationDbContext** to derive from **MySqlDatabase** and include a constructor that take a single parameter with the connection name.

```
public class ApplicationDbContext : MySQLDatabase
{
    public ApplicationDbContext(string connectionName)
        : base(connectionName)
    {
    }

    public static ApplicationDbContext Create()
    {
        return new ApplicationDbContext("DefaultConnection");
    }
}
```

8. Open the IdentityConfig.cs file. In the **ApplicationUserManager.Create** method, replace instantiating UserManager with the following code:

```
var manager = new ApplicationUserManager(
    new UserStore<ApplicationUser>(
    context.Get<ApplicationDbContext>() as MySQLDatabase));
```

9. Open the web.config file and replace the DefaultConnection string with this entry replacing the highlighted values with the connection string of the MySQL database you created on previous steps:

```
<add name="DefaultConnection" connectionString="Database=IdentityMySQLDatabase;
Data Source=<DataSource>;User Id=<UserID>;Password=<Password>"
providerName="MySql.Data.MySqlClient" />
```

Run the app and connect to the MySQL DB

1. Right click the **IdentityMySQLDemo** project and select **Set as Startup Project**
2. Press **Ctrl + F5** to build and run the app.
3. Click on **Register** tab on the top of the page.
4. Enter a new user name and password and then click on **Register**.

5. The new user is now registered and logged in.

6. Go back to the MySQL Workbench tool and inspect the **IdentityMySQLDatabase** table's contents. Inspect the users table for the entries as you register new users.

Id	Email	EmailConfirmed	PasswordHash	SecurityStamp	PhoneNumber	PhoneN
c41...	ExampleUser@contoso.com	0	ANTovduTgXFtM...	edb5c55e-2a69-...	NULL	0
NULL	NULL	NULL	NULL	NULL	NULL	NULL

Next Steps

For more information on how to enable other authentication methods on this app, refer to Create an ASP.NET MVC 5 App with Facebook and Google OAuth2 and OpenID Sign-on.

To learn how to integrate your DB with OAuth and to set up roles to limit users access to your app, see Deploy a Secure ASP.NET MVC 5 app with Membership, OAuth, and SQL Database to Azure.

Change Primary Key for Users in ASP.NET Identity

2/20/2020 • 20 minutes to read • Edit Online

by Tom FitzMacken

In Visual Studio 2013, the default web application uses a string value for the key for user accounts. ASP.NET Identity enables you to change the type of the key to meet your data requirements. For example, you can change the type of the key from a string to an integer.

This topic shows how to start with the default web application and change the user account key to an integer. You can use the same modifications to implement any type of key in your project. It shows how to make these changes in the default web application, but you could apply similar modifications to a customized application. It shows the changes needed when working with MVC or Web Forms.

Software versions used in the tutorial

- Visual Studio 2013 with Update 2 (or later)
- ASP.NET Identity 2.1 or later

To perform the steps in this tutorial, you must have Visual Studio 2013 Update 2 (or later), and a web application created from the ASP.NET Web Application template. The template changed in Update 3. This topic shows how to change the template in Update 2 and Update 3.

This topic contains the following sections:

- Change the type of the key in the Identity user class
- Add customized Identity classes that use the key type
- Change the context class and user manager to use the key type
- Change start-up configuration to use the key type
- For MVC with Update 2, change the AccountController to pass the key type
- For MVC with Update 3, change the AccountController and ManageController to pass the key type
- For Web Forms with Update 2, change Account pages to pass the key type
- For Web Forms with Update 3, change Account pages to pass the key type
- Run application
- Other resources

Change the type of the key in the Identity user class

In your project created from the ASP.NET Web Application template, specify that the ApplicationUser class uses an integer for the key for user accounts. In IdentityModels.cs, change the ApplicationUser class to inherit from IdentityUser that has a type of **int** for the TKey generic parameter. You also pass the names of three customized class which you have not implemented yet.

```
public class ApplicationUser : IdentityUser<int, CustomUserLogin, CustomUserRole,
    CustomUserClaim>
{
    ...
```

You have changed the type of the key, but, by default, the rest of the application still assumes the key is a string.

You must explicitly indicate the type of the key in code that assumes a string.

In the **ApplicationUser** class, change the **GenerateUserIdentityAsync** method to include int, as shown in the highlighted code below. This change is not necessary for Web Forms projects with the Update 3 template.

```
public async Task<ClaimsIdentity> GenerateUserIdentityAsync(
    UserManager<ApplicationUser, int> manager)
{
    // Note the authenticationType must match the one defined in
    // CookieAuthenticationOptions.AuthenticationType
    var userIdentity = await manager.CreateIdentityAsync(
        this, DefaultAuthenticationTypes.ApplicationCookie);
    // Add custom user claims here
    return userIdentity;
}
```

Add customized Identity classes that use the key type

The other Identity classes, such as IdentityUserRole, IdentityUserClaim, IdentityUserLogin, IdentityRole, UserStore, RoleStore, are still set up to use a string key. Create new versions of these classes that specify an integer for the key. You do not need to provide much implementation code in these classes, you are primarily just setting int as the key.

Add the following classes to your IdentityModels.cs file.

```
public class CustomUserRole : IdentityUserRole<int> { }
public class CustomUserClaim : IdentityUserClaim<int> { }
public class CustomUserLogin : IdentityUserLogin<int> { }

public class CustomRole : IdentityRole<int, CustomUserRole>
{
    public CustomRole() { }
    public CustomRole(string name) { Name = name; }
}

public class CustomUserStore : UserStore<ApplicationUser, CustomRole, int,
    CustomUserLogin, CustomUserRole, CustomUserClaim>
{
    public CustomUserStore(ApplicationDbContext context)
        : base(context)
    {
    }
}

public class CustomRoleStore : RoleStore<CustomRole, int, CustomUserRole>
{
    public CustomRoleStore(ApplicationDbContext context)
        : base(context)
    {
    }
}
```

Change the context class and user manager to use the key type

In IdentityModels.cs, change the definition of the **ApplicationDbContext** class to use your new customized classes and an **int** for the key, as shown in the highlighted code.

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser, CustomRole,
    int, CustomUserLogin, CustomUserRole, CustomUserClaim>
{
    ...
```

The ThrowIfV1Schema parameter is no longer valid in the constructor. Change the constructor so it does not pass a ThrowIfV1Schema value.

```
public ApplicationDbContext()
    : base("DefaultConnection")
{
}
```

Open IdentityConfig.cs, and change the **ApplicationUserManger** class to use your new user store class for persisting data and an **int** for the key.

```
public class ApplicationUserManager : UserManager<ApplicationUser, int>
{
    public ApplicationUserManager(IUserStore<ApplicationUser, int> store)
        : base(store)
    {
    }

    public static ApplicationUserManager Create(
        IdentityFactoryOptions<ApplicationUserManager> options, IOwinContext context)
    {
        var manager = new ApplicationUserManager(
            new CustomUserStore(context.Get<ApplicationDbContext>()));
        // Configure validation logic for usernames
        manager.UserValidator = new UserValidator<ApplicationUser, int>(manager)
        {
            AllowOnlyAlphanumericUserNames = false,
            RequireUniqueEmail = true
        };
        // Configure validation logic for passwords
        manager.PasswordValidator = new PasswordValidator
        {
            RequiredLength = 6,
            RequireNonLetterOrDigit = true,
            RequireDigit = true,
            RequireLowercase = true,
            RequireUppercase = true,
        };
        // Register two factor authentication providers. This application uses Phone
        // and Emails as a step of receiving a code for verifying the user
        // You can write your own provider and plug in here.
        manager.RegisterTwoFactorProvider("PhoneCode",
            new PhoneNumberTokenProvider<ApplicationUser, int>
        {
            MessageFormat = "Your security code is: {0}"
        });
        manager.RegisterTwoFactorProvider("EmailCode",
            new EmailTokenProvider<ApplicationUser, int>
        {
            Subject = "Security Code",
            BodyFormat = "Your security code is: {0}"
        });
        manager.EmailService = new EmailService();
        manager.SmsService = new SmsService();
        var dataProtectionProvider = options.DataProtectionProvider;
        if (dataProtectionProvider != null)
        {
            manager.UserTokenProvider =
                new DataProtectorTokenProvider<ApplicationUser, int>(
                    dataProtectionProvider.Create("ASP.NET Identity"));
        }
        return manager;
    }
}
```

In the Update 3 template, you must change the ApplicationSignInManager class.

```
public class ApplicationSignInManager : SignInManager<ApplicationUser, int>
{ ... }
```

Change start-up configuration to use the key type

In Startup.Auth.cs, replace the OnValidateIdentity code, as highlighted below. Notice that the getUserIdCallback definition, parses the string value into an integer.

```
app.UseCookieAuthentication(new CookieAuthenticationOptions
    {
        AuthenticationType = DefaultAuthenticationTypes.ApplicationCookie,
        LoginPath = new PathString("/Account/Login"),
        Provider = new CookieAuthenticationProvider
        {
            OnValidateIdentity = SecurityStampValidator
                .OnValidateIdentity<ApplicationUserManager, ApplicationUser, int>(
                    validateInterval: TimeSpan.FromMinutes(30),
                    regenerateIdentityCallback: (manager, user) =>
                        user.GenerateUserIdentityAsync(manager),
                    getUserIdCallback:(id)=>(id.GetUserId<int>()))
        }
    });
```

If your project does not recognize the generic implementation of the **GetUserId** method, you may need to update the ASP.NET Identity NuGet package to version 2.1

You have made a lot of changes to the infrastructure classes used by ASP.NET Identity. If you try compiling the project, you will notice a lot of errors. Fortunately, the remaining errors are all similar. The Identity class expects an integer for the key, but the controller (or Web Form) is passing a string value. In each case, you need to convert from a string to and integer by calling **GetUserId<int>**. You can either work through the error list from compilation or follow the changes below.

The remaining changes depend on the type of project you are creating and which update you have installed in Visual Studio. You can go directly to the relevant section through the following links

- For MVC with Update 2, change the AccountController to pass the key type
- For MVC with Update 3, change the AccountController and ManageController to pass the key type
- For Web Forms with Update 2, change Account pages to pass the key type
- For Web Forms with Update 3, change Account pages to pass the key type

For MVC with Update 2, change the AccountController to pass the key type

Open the AccountController.cs file. You need to change the following methods.

ConfirmEmail method

```
public async Task<ActionResult> ConfirmEmail(int userId, string code)
{
    if (userId == default(int) || code == null)
    {
        return View("Error");
    }

    IdentityResult result = await UserManager.ConfirmEmailAsync(userId, code);
    if (result.Succeeded)
    {
        return View("ConfirmEmail");
    }
    else
    {
        AddErrors(result);
        return View();
    }
}
```

Disassociate method

```
public async Task<ActionResult> Disassociate(string loginProvider, string providerKey)
{
    ManageMessageId? message = null;
    IdentityResult result = await UserManager.RemoveLoginAsync(
        User.Identity.GetUserId<int>(),
        new UserLoginInfo(loginProvider, providerKey));
    if (result.Succeeded)
    {
        var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
        await SignInAsync(user, isPersistent: false);
        message = ManageMessageId.RemoveLoginSuccess;
    }
    else
    {
        message = ManageMessageId.Error;
    }
    return RedirectToAction("Manage", new { Message = message });
}
```

Manage(ManageUserViewModel) method

```
public async Task<ActionResult> Manage(ManageUserViewModel model)
{
    bool hasPassword = HasPassword();
    ViewBag.HasLocalPassword = hasPassword;
    ViewBag.ReturnUrl = Url.Action("Manage");
    if (hasPassword)
    {
        if (ModelState.IsValid)
        {
            IdentityResult result = await UserManager.ChangePasswordAsync(
                User.Identity.GetUserId<int>(),
                model.OldPassword,
                model.NewPassword);
            if (result.Succeeded)
            {
                var user = await UserManager.FindByIdAsync(
                  User.Identity.GetUserId<int>());
                await SignInAsync(user, isPersistent: false);
                return RedirectToAction("Manage", new {
                    Message = ManageMessageId.ChangePasswordSuccess });
            }
            else
            {
                AddErrors(result);
            }
        }
    }
    else
    {
        // User does not have a password so remove any validation errors caused
        // by a missing OldPassword field
        ModelState state = ModelState["OldPassword"];
        if (state != null)
        {
            state.Errors.Clear();
        }

        if (ModelState.IsValid)
        {
            IdentityResult result = await UserManager.AddPasswordAsync(
                User.Identity.GetUserId<int>(), model.NewPassword);
            if (result.Succeeded)
            {
                return RedirectToAction("Manage", new {
                    Message = ManageMessageId.SetPasswordSuccess });
            }
            else
            {
                AddErrors(result);
            }
        }
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

LinkLoginCallback method

```
public async Task<ActionResult> LinkLoginCallback()
{
    var loginInfo = await AuthenticationManager.GetExternalLoginInfoAsync(XsrfKey,
        User.Identity.GetUserId());
    if (loginInfo == null)
    {
        return RedirectToAction("Manage", new { Message = ManageMessageId.Error });
    }
    IdentityResult result = await UserManager.AddLoginAsync(
        User.Identity.GetUserId<int>(), loginInfo.Login);
    if (result.Succeeded)
    {
        return RedirectToAction("Manage");
    }
    return RedirectToAction("Manage", new { Message = ManageMessageId.Error });
}
```

RemoveAccountList method

```
public ActionResult RemoveAccountList()
{
    var linkedAccounts = UserManager.GetLogins(User.Identity.GetUserId<int>());
    ViewBag.ShowRemoveButton = HasPassword() || linkedAccounts.Count > 1;
    return (ActionResult)PartialView("_RemoveAccountPartial", linkedAccounts);
}
```

HasPassword method

```
private bool HasPassword()
{
    var user = UserManager.FindById(User.Identity.GetUserId<int>());
    if (user != null)
    {
        return user.PasswordHash != null;
    }
    return false;
}
```

You can now run the application and register a new user.

For MVC with Update 3, change the AccountController and ManageController to pass the key type

Open the AccountController.cs file. You need to change the following method.

ConfirmEmail method

```
public async Task<ActionResult> ConfirmEmail(int userId, string code)
{
    if (userId == default(int) || code == null)
    {
        return View("Error");
    }

    IdentityResult result = await UserManager.ConfirmEmailAsync(userId, code);
    return View(result.Succeeded ? "ConfirmEmail" : "Error");
}
```

SendCode method

```
public async Task<ActionResult> SendCode(string returnUrl, bool rememberMe)
{
    var userId = await SignInManager.GetVerifiedUserIdAsync();
    if (userId == default(int))
    {
        return View("Error");
    }
    var userFactors = await UserManager.GetValidTwoFactorProvidersAsync(userId);
    var factorOptions = userFactors.Select(purpose => new SelectListItem { Text = purpose, Value = purpose
}).ToList();
    return View(new SendCodeViewModel { Providers = factorOptions, ReturnUrl = returnUrl, RememberMe =
rememberMe });
}
```

Open the ManageController.cs file. You need to change the following methods.

Index method

```
public async Task<ActionResult> Index(ManageMessageId? message)
{
    ViewBag.StatusMessage =
        message == ManageMessageId.ChangePasswordSuccess ? "Your password has been changed."
        : message == ManageMessageId.SetPasswordSuccess ? "Your password has been set."
        : message == ManageMessageId.SetTwoFactorSuccess ? "Your two-factor authentication provider has been
set."
        : message == ManageMessageId.Error ? "An error has occurred."
        : message == ManageMessageId.AddPhoneSuccess ? "Your phone number was added."
        : message == ManageMessageId.RemovePhoneSuccess ? "Your phone number was removed."
        : "";

    var model = new IndexViewModel
    {
        HasPassword = HasPassword(),
        PhoneNumber = await UserManager.GetPhoneNumberAsync(User.Identity.GetUserId<int>()),
        TwoFactor = await UserManager.GetTwoFactorEnabledAsync(User.Identity.GetUserId<int>()),
        Logins = await UserManager.GetLoginsAsync(User.Identity.GetUserId<int>()),
        BrowserRemembered = await AuthenticationManager.TwoFactorBrowserRememberedAsync(
          User.Identity.GetUserId())
    };
    return View(model);
}
```

RemoveLogin methods

```
public ActionResult RemoveLogin()
{
    var linkedAccounts = UserManager.GetLogins((User.Identity.GetUserId<int>()));
    ViewBag.ShowRemoveButton = HasPassword() || linkedAccounts.Count > 1;
    return View(linkedAccounts);
}

[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> RemoveLogin(string loginProvider, string providerKey)
{
    ManageMessageId? message;
    var result = await UserManager.RemoveLoginAsync(User.Identity.GetUserId<int>(),
        new UserLoginInfo(loginProvider, providerKey));
    if (result.Succeeded)
    {
        var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
        if (user != null)
        {
            await SignInAsync(user, isPersistent: false);
        }
        message = ManageMessageId.RemoveLoginSuccess;
    }
    else
    {
        message = ManageMessageId.Error;
    }
    return RedirectToAction("ManageLogins", new { Message = message });
}
```

AddPhoneNumber method

```
public async Task<ActionResult> AddPhoneNumber(AddPhoneNumberViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }
    // Generate the token and send it
    var code = await UserManager.GenerateChangePhoneNumberTokenAsync(
        User.Identity.GetUserId<int>(), model.Number);
    if (UserManager.SmsService != null)
    {
        var message = new IdentityMessage
        {
            Destination = model.Number,
            Body = "Your security code is: " + code
        };
        await UserManager.SmsService.SendAsync(message);
    }
    return RedirectToAction("VerifyPhoneNumber", new { PhoneNumber = model.Number });
}
```

EnableTwoFactorAuthentication method

```
public async Task<ActionResult> EnableTwoFactorAuthentication()
{
    await UserManager.SetTwoFactorEnabledAsync(User.Identity.GetUserId<int>(), true);
    var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
    if (user != null)
    {
        await SignInAsync(user, isPersistent: false);
    }
    return RedirectToAction("Index", "Manage");
}
```

DisableTwoFactorAuthentication method

```
public async Task<ActionResult> DisableTwoFactorAuthentication()
{
    await UserManager.SetTwoFactorEnabledAsync(User.Identity.GetUserId<int>(), false);
    var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
    if (user != null)
    {
        await SignInAsync(user, isPersistent: false);
    }
    return RedirectToAction("Index", "Manage");
}
```

VerifyPhoneNumber methods

```
public async Task<ActionResult> VerifyPhoneNumber(string phoneNumber)
{
    var code = await UserManager.GenerateChangePhoneNumberTokenAsync(
        User.Identity.GetUserId<int>(), phoneNumber);
    // Send an SMS through the SMS provider to verify the phone number
    return phoneNumber == null ? View("Error") : View(new VerifyPhoneNumberViewModel { PhoneNumber =
phoneNumber });
}

[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> VerifyPhoneNumber(VerifyPhoneNumberViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }
    var result = await UserManager.ChangePhoneNumberAsync(
        User.Identity.GetUserId<int>(), model.PhoneNumber, model.Code);
    if (result.Succeeded)
    {
        var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
        if (user != null)
        {
            await SignInAsync(user, isPersistent: false);
        }
        return RedirectToAction("Index", new { Message = ManageMessageId.AddPhoneSuccess });
    }
    // If we got this far, something failed, redisplay form
    ModelState.AddModelError("", "Failed to verify phone");
    return View(model);
}
```

RemovePhoneNumber method

```
public async Task<ActionResult> RemovePhoneNumber()
{
    var result = await UserManager.SetPhoneNumberAsync(User.Identity.GetUserId<int>(), null);
    if (!result.Succeeded)
    {
        return RedirectToAction("Index", new { Message = ManageMessageId.Error });
    }
    var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
    if (user != null)
    {
        await SignInAsync(user, isPersistent: false);
    }
    return RedirectToAction("Index", new { Message = ManageMessageId.RemovePhoneSuccess });
}
```

ChangePassword method

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> ChangePassword(ChangePasswordViewModel model)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }
    var result = await UserManager.ChangePasswordAsync(
        User.Identity.GetUserId<int>(), model.OldPassword, model.NewPassword);
    if (result.Succeeded)
    {
        var user = await UserManager.FindByIdAsync(User.Identity.GetUserId<int>());
        if (user != null)

    return View(new ManageLoginsViewModel
    {
        CurrentLogins = userLogins,
        OtherLogins = otherLogins
    });
}
```

LinkLoginCallback method

```
public async Task<ActionResult> LinkLoginCallback()
{
    var loginInfo = await AuthenticationManager.GetExternalLoginInfoAsync(XsrfKey,
User.Identity.GetUserId());
    if (loginInfo == null)
    {
        return RedirectToAction("ManageLogins", new { Message = ManageMessageId.Error });
    }
    var result = await UserManager.AddLoginAsync(User.Identity.GetUserId<int>(),
        loginInfo.Login);
    return result.Succeeded ? RedirectToAction("ManageLogins") :
        RedirectToAction("ManageLogins", new { Message = ManageMessageId.Error });
}
```

HasPassword method

```
private bool HasPassword()
{
    var user = UserManager.FindById(User.Identity.GetUserId<int>());
    if (user != null)
    {
        return user.PasswordHash != null;
    }
    return false;
}
```

HasPhoneNumber method

```
private bool HasPhoneNumber()
{
    var user = UserManager.FindById(User.Identity.GetUserId<int>());
    if (user != null)
    {
        return user.PhoneNumber != null;
    }
    return false;
}
```

You can now run the application and register a new user.

For Web Forms with Update 2, change Account pages to pass the key type

For Web Forms with Update 2, you need to change the following pages.

Confirm.aspx.cx

```
protected void Page_Load(object sender, EventArgs e)
{
    string code = IdentityHelper.GetCodeFromRequest(Request);
    string userId = IdentityHelper.GetUserIdFromRequest(Request);
    if (code != null && userId != null)
    {
        var manager = Context.GetOwinContext().GetUserManager<ApplicationUserManager>();
        var result = manager.ConfirmEmail(Int32.Parse(userId), code);
        if (result.Succeeded)
        {
            StatusMessage = "Thank you for confirming your account.";
            return;
        }
    }

    StatusMessage = "An error has occurred";
}
```

RegisterExternalLogin.aspx.cs

```
protected void Page_Load()
{
    // Process the result from an auth provider in the request
    ProviderName = IdentityHelper.GetProviderNameFromRequest(Request);
    if (String.IsNullOrEmpty(ProviderName))
    {
        RedirectOnFail();
        return;
    }
    if (!IsPostBack)

        sendcode.Visible = false;
        verifycode.Visible = true;
    }
}
```

Run application

You have finished all of the required changes to the default Web Application template. Run the application and register a new user. After registering the user, you will notice that the AspNetUsers table has an Id column that is an integer.

If you have previously created the ASP.NET Identity tables with a different primary key, you need to make some additional changes. If possible, just delete the existing database. The database will be re-created with the correct design when you run the web application and add a new user. If deletion is not possible, run code first migrations to change the tables. However, the new integer primary key will not be set up as a SQL IDENTITY property in the database. You must manually set the Id column as an IDENTITY.

Migrating an Existing Website from SQL Membership to ASP.NET Identity

2/20/2020 • 16 minutes to read • Edit Online

by Rick Anderson, Suhas Joshi

This tutorial illustrates the steps to migrate an existing web application with user and role data created using SQL Membership to the new ASP.NET Identity system. This approach involves changing the existing database schema to the one needed by the ASP.NET Identity and hook in the old/new classes to it. After you adopt this approach, once your database is migrated, future updates to Identity will be handled effortlessly.

For this tutorial, we will take a web application template (Web Forms) created using Visual Studio 2010 to create user and role data. We will then use SQL scripts to migrate the existing database to tables needed by the Identity system. Next we'll install the necessary NuGet packages and add new account management pages which use the Identity system for membership management. As a test of migration, users created using SQL membership should be able to log in and new users should be able to register. You can find the complete sample here. See also Migrating from ASP.NET Membership to ASP.NET Identity.

Getting started

Creating an application with SQL Membership

1. We need to start with an existing application that uses SQL membership and has user and role data. For the purpose of this article, let's create a web application in Visual Studio 2010.

2. Using the ASP.NET Configuration tool, create 2 users: **oldAdminUser** and **oldUser**.

3. Create a role named Admin and add 'oldAdminUser' as a user in that role.

4. Create an Admin section of the site with a Default.aspx. Set the authorization tag in the web.config file to enable access only to users in Admin roles. More information can be found here https://www.asp.net/web-forms/tutorials/security/roles/role-based-authorization-cs

5. View the database in Server Explorer to understand the tables created by the SQL membership system. The user login data is stored in the aspnet_Users and aspnet_Membership tables, while role data is stored in the aspnet_Roles table. Information about which users are in which roles is stored in the aspnet_UsersInRoles table. For basic membership management it is sufficient to port the information in the above tables to the ASP.NET Identity system.

Migrating to Visual Studio 2013

1. Install Visual Studio Express 2013 for Web or Visual Studio 2013 along with the latest updates.

2. Open the above project in your installed version of Visual Studio. If SQL Server Express is not installed on the machine, a prompt is displayed when you open the project, since the connection string uses SQL Express. You can either choose to install SQL Express or as work around change the connection string to LocalDb. For this article we'll change it to LocalDb.

3. Open web.config and change the connection string from .SQLExpress to (LocalDb)v11.0. Remove 'User Instance=true' from the connection string.

```
<configuration>
  <connectionStrings>
    <add name="ApplicationServices"
         connectionString="data source=(LocalDb)\v11.0;Integrated Security=SSPI;AttachDBFilename=|DataDirectory|\aspnetdb.mdf
         providerName="System.Data.SqlClient" />
  </connectionStrings>
```

4. Open Server Explorer and verify that the table schema and data can be observed.

5. The ASP.NET Identity system works with version 4.5 or higher of the framework. Retarget the application to 4.5 or higher.

Build the project to verify that there are no errors.

Installing the Nuget packages

1. In Solution Explorer, right-click the project > **Manage NuGet Packages**. In the search box, enter "Asp.net Identity". Select the package in the list of results and click install. Accept the license agreement by clicking on "I Accept" button. Note that this package will install the dependency packages: EntityFramework and Microsoft ASP.NET Identity Core. Similarly install the following packages (skip the last 4 OWIN packages if you don't want to enable OAuth log-in):

   - Microsoft.AspNet.Identity.Owin
   - Microsoft.Owin.Host.SystemWeb
   - Microsoft.Owin.Security.Facebook
   - Microsoft.Owin.Security.Google
   - Microsoft.Owin.Security.MicrosoftAccount
   - Microsoft.Owin.Security.Twitter

Migrate database to the new Identity system

The next step is to migrate the existing database to a schema required by the ASP.NET Identity system. To achieve this we run a SQL script which has a set of commands to create new tables and migrate existing user information

to the new tables. The script file can be found here.

This script file is specific to this sample. If the schema for the tables created using SQL membership is customized or modified the scripts need to be changed accordingly.

How to generate the SQL script for schema migration

For ASP.NET Identity classes to work out of the box with the data of existing users, we need to migrate the database schema to the one needed by ASP.NET Identity. We can do this by adding new tables and copying the existing information to those tables. By default ASP.NET Identity uses EntityFramework to map the Identity model classes back to the database to store/retrieve information. These model classes implement the core Identity interfaces defining user and role objects. The tables and the columns in the database are based on these model classes. The EntityFramework model classes in Identity v2.1.0 and their properties are as defined below

IDENTITYUSER	TYPE	IDENTITYROLE	IDENTITYUSERROLE	IDENTITYUSERLOGIN	IDENTITYUSERCLAIM
Id	string	Id	RoleId	ProviderKey	Id
Username	string	Name	UserId	UserId	ClaimType
PasswordHash	string			LoginProvider	ClaimValue
SecurityStamp	string				User_Id
Email	string				
EmailConfirmed	bool				
PhoneNumber	string				
PhoneNumberConfirmed	bool				
LockoutEnabled	bool				
LockoutEndDate	DateTime				
AccessFailedCount	int				

We need to have tables for each of these models with columns corresponding to the properties. The mapping between classes and tables is defined in the `OnModelCreating` method of the `IdentityDBContext`. This is known as the fluent API method of configuration and more information can be found here. The configuration for the classes is as mentioned below

CLASS	TABLE	PRIMARY KEY	FOREIGN KEY
IdentityUser	AspnetUsers	Id	
IdentityRole	AspnetRoles	Id	
IdentityUserRole	AspnetUserRole	UserId + RoleId	User_Id->AspnetUsers RoleId->AspnetRoles

CLASS	TABLE	PRIMARY KEY	FOREIGN KEY
IdentityUserLogin	AspnetUserLogins	ProviderKey+UserId + LoginProvider	UserId->AspnetUsers
IdentityUserClaim	AspnetUserClaims	Id	User_Id->AspnetUsers

With this information we can create SQL statements to create new tables. We can either write each statement individually or generate the entire script using EntityFramework PowerShell commands which we can then edit as required. To do this, in VS open the **Package Manager Console** from the **View** or **Tools** menu

- Run command "Enable-Migrations" to enable EntityFramework migrations.
- Run command "Add-migration initial" which creates the initial setup code to create the database in C#/VB.
- The final step is to run "Update-Database –Script" command that generates the SQL script based on the model classes.

> Some commands aren't supported if the app uses SQLite as its Identity data store. Due to limitations in the database engine, `Alter` commands throw the following exception:
>
> "System.NotSupportedException: SQLite does not support this migration operation."
>
> As a work around, run Code First migrations on the database to change the tables.

This database generation script can be used as a start where we'll be making additional changes to add new columns and copy data. The advantage of this is that we generate the `_MigrationHistory` table which is used by EntityFramework to modify the database schema when the model classes change for future versions of Identity releases.

The SQL membership user information had other properties in addition to the ones in the Identity user model class namely email, password attempts, last login date, last lock-out date etc. This is useful information and we would like it to be carried over to the Identity system. This can be done by adding additional properties to the user model and mapping them back to the table columns in the database. We can do this by adding a class that subclasses the `IdentityUser` model. We can add the properties to this custom class and edit the SQL script to add the corresponding columns when creating the table. The code for this class is described further in the article. The SQL script for creating the `AspnetUsers` table after adding the new properties would be

```
CREATE TABLE [dbo].[AspNetUsers] (
    [Id]            NVARCHAR (128) NOT NULL,
    [UserName]      NVARCHAR (MAX) NULL,
    [PasswordHash]  NVARCHAR (MAX) NULL,
    [SecurityStamp] NVARCHAR (MAX) NULL,
    [EmailConfirmed]       BIT            NOT NULL,
    [PhoneNumber]          NVARCHAR (MAX) NULL,
    [PhoneNumberConfirmed] BIT            NOT NULL,
    [TwoFactorEnabled]     BIT            NOT NULL,
    [LockoutEndDateUtc]    DATETIME       NULL,
    [LockoutEnabled]       BIT            NOT NULL,
    [AccessFailedCount]    INT            NOT NULL,
    [ApplicationId]                          UNIQUEIDENTIFIER NOT NULL,
    [LegacyPasswordHash]  NVARCHAR (MAX) NULL,
    [LoweredUserName]  NVARCHAR (256)   NOT NULL,
    [MobileAlias]      NVARCHAR (16)    DEFAULT (NULL) NULL,
    [IsAnonymous]      BIT              DEFAULT ((0)) NOT NULL,
    [LastActivityDate] DATETIME2         NOT NULL,
    [MobilePIN]                              NVARCHAR (16)    NULL,
    [Email]                                  NVARCHAR (256)   NULL,
    [LoweredEmail]                           NVARCHAR (256)   NULL,
    [PasswordQuestion]                       NVARCHAR (256)   NULL,
    [PasswordAnswer]                         NVARCHAR (128)   NULL,
    [IsApproved]                             BIT              NOT NULL,
    [IsLockedOut]                            BIT              NOT NULL,
    [CreateDate]                             DATETIME2               NOT NULL,
    [LastLoginDate]                          DATETIME2         NOT NULL,
    [LastPasswordChangedDate]                DATETIME2         NOT NULL,
    [LastLockoutDate]                        DATETIME2         NOT NULL,
    [FailedPasswordAttemptCount]             INT              NOT NULL,
    [FailedPasswordAttemptWindowStart]       DATETIME2         NOT NULL,
    [FailedPasswordAnswerAttemptCount]       INT              NOT NULL,
    [FailedPasswordAnswerAttemptWindowStart] DATETIME2         NOT NULL,
    [Comment]                                NTEXT            NULL,
    CONSTRAINT [PK_dbo.AspNetUsers] PRIMARY KEY CLUSTERED ([Id] ASC),
    FOREIGN KEY ([ApplicationId]) REFERENCES [dbo].[aspnet_Applications] ([ApplicationId]),
);
```

Next we need to copy the existing information from the SQL membership database to the newly added tables for Identity. This can be done through SQL by copying data directly from one table to another. To add data into the rows of table, we use the `INSERT INTO [Table]` construct. To copy from another table we can use the `INSERT INTO` statement along with the `SELECT` statement. To get all the user information we need to query the *aspnet_Users* and *aspnet_Membership* tables and copy the data to the *AspNetUsers* table. We use the `INSERT INTO` and `SELECT` along with `JOIN` and `LEFT OUTER JOIN` statements. For more information about querying and copying data between tables, refer to this link. Additionally the AspnetUserLogins and AspnetUserClaims tables are empty to begin with since there is no information in SQL membership that maps to this by default. The only information copied is for users and roles. For the project created in the previous steps, the SQL query to copy information to the users table would be

```
INSERT INTO AspNetUsers(Id,UserName,PasswordHash,SecurityStamp,EmailConfirmed,
PhoneNumber,PhoneNumberConfirmed,TwoFactorEnabled,LockoutEndDateUtc,LockoutEnabled,AccessFailedCount,
ApplicationId,LoweredUserName,MobileAlias,IsAnonymous,LastActivityDate,LegacyPasswordHash,
MobilePIN,Email,LoweredEmail,PasswordQuestion,PasswordAnswer,IsApproved,IsLockedOut,CreateDate,
LastLoginDate,LastPasswordChangedDate,LastLockoutDate,FailedPasswordAttemptCount,
FailedPasswordAnswerAttemptWindowStart,FailedPasswordAnswerAttemptCount,FailedPasswordAttemptWindowStart,Comm
ent)
SELECT aspnet_Users.UserId,aspnet_Users.UserName,
(aspnet_Membership.Password+'|'+CAST(aspnet_Membership.PasswordFormat as
varchar)+'|'+aspnet_Membership.PasswordSalt),NewID(),
'true',NULL,'false','true',aspnet_Membership.LastLockoutDate,'true','0',
aspnet_Users.ApplicationId,aspnet_Users.LoweredUserName,
aspnet_Users.MobileAlias,aspnet_Users.IsAnonymous,aspnet_Users.LastActivityDate,aspnet_Membership.Password,
aspnet_Membership.MobilePIN,aspnet_Membership.Email,aspnet_Membership.LoweredEmail,aspnet_Membership.Password
Question,aspnet_Membership.PasswordAnswer,
aspnet_Membership.IsApproved,aspnet_Membership.IsLockedOut,aspnet_Membership.CreateDate,aspnet_Membership.Las
tLoginDate,aspnet_Membership.LastPasswordChangedDate,
aspnet_Membership.LastLockoutDate,aspnet_Membership.FailedPasswordAttemptCount,
aspnet_Membership.FailedPasswordAnswerAttemptWindowStart,
aspnet_Membership.FailedPasswordAnswerAttemptCount,aspnet_Membership.FailedPasswordAttemptWindowStart,aspnet_
Membership.Comment
FROM aspnet_Users
LEFT OUTER JOIN aspnet_Membership ON aspnet_Membership.ApplicationId = aspnet_Users.ApplicationId
AND aspnet_Users.UserId = aspnet_Membership.UserId;
```

In the above SQL statement, information about each user from the *aspnet_Users* and *aspnet_Membership* tables is copied into the columns of the *AspnetUsers* table. The only modification done here is when we copy the password. Since the encryption algorithm for passwords in SQL membership used 'PasswordSalt' and 'PasswordFormat', we copy that too along with the hashed password so that it can be used to decrypt the password by Identity. This is explained further in the article when hooking up a custom password hasher.

This script file is specific to this sample. For applications which have additional tables, developers can follow a similar approach to add additional properties on the user model class and map them to columns in the AspnetUsers table. To run the script,

1. Open Server Explorer. Expand the 'ApplicationServices' connection to display the tables. Right click on the Tables node and select the 'New Query' option

2. In the query window, copy and paste the entire SQL script from the Migrations.sql file. Run the script file by hitting the 'Execute' arrow button.

```
SQLQuery1.sql *
B1615B31750BE7C9C207609833D8(
DROP TABLE AspNetUserRoles;

DROP TABLE AspNetUserClaims;

DROP TABLE AspNetUserLogins;

DROP TABLE AspNetRoles;

DROP TABLE AspNetUsers;

CREATE TABLE [dbo].[AspNetUsers] (
    [Id]              NVARCHAR (128) NOT NULL,
    [UserName]        NVARCHAR (MAX) NULL,
    [PasswordHash]    NVARCHAR (MAX) NULL,
    [SecurityStamp]   NVARCHAR (MAX) NULL,
    [Discriminator]   NVARCHAR (128) NOT NULL,
    [ApplicationId]                          UNIQUEIDENTIFIER NOT NULL,
    [PasswordFormat]                         INT              DEFAULT ((0)) NULL,
    [PasswordSalt]                           NVARCHAR (128)   NULL,
    [LegacyPasswordHash]  NVARCHAR (MAX) NULL,
    [LoweredUserName]  NVARCHAR (256)   NOT NULL,
    [MobileAlias]      NVARCHAR (16)    DEFAULT (NULL) NULL,
    [IsAnonymous]      BIT              DEFAULT ((0)) NOT NULL,
    [LastActivityDate] DATETIME         NOT NULL,
    [MobilePIN]                              NVARCHAR (16)    NULL,
    [Email]                                  NVARCHAR (256)   NULL,
    [LoweredEmail]                           NVARCHAR (256)   NULL,
    [PasswordQuestion]                       NVARCHAR (256)   NULL,
    [PasswordAnswer]                         NVARCHAR (128)   NULL,
    [IsApproved]                             BIT              NOT NULL,
    [IsLockedOut]                            BIT              NOT NULL,
    [CreateDate]                             DATETIME         NOT NULL,
    [LastLoginDate]                          DATETIME         NOT NULL,
    [LastPasswordChangedDate]                DATETIME         NOT NULL,
    [LastLockoutDate]                        DATETIME         NOT NULL,
    [FailedPasswordAttemptCount]             INT              NOT NULL,
    [FailedPasswordAttemptWindowStart]       DATETIME         NOT NULL,
    [FailedPasswordAnswerAttemptCount]       INT              NOT NULL,
100 %
```

Refresh the Server Explorer window. Five new tables are created in the database.

```
SQLQuery1.sql *   User.cs
C8D7444F4FA827C3FB15138DF9C8
IF OBJECT_ID('AspNetUserRoles', 'U') IS NOT NULL
BEGIN
  DROP TABLE AspNetUserRoles;
  END

IF OBJECT_ID('AspNetUserClaims', 'U') IS NOT NULL
BEGIN
  DROP TABLE AspNetUserClaims;
  END

IF OBJECT_ID('AspNetUserLogins', 'U') IS NOT NULL
BEGIN
  DROP TABLE AspNetUserLogins;
  END

IF OBJECT_ID('AspNetRoles', 'U') IS NOT NULL
BEGIN
  DROP TABLE AspNetRoles;
  END

IF OBJECT_ID('AspNetUsers', 'U') IS NOT NULL
BEGIN
  DROP TABLE AspNetUsers;
  END

CREATE TABLE [dbo].[AspNetUsers] (
    [Id]              NVARCHAR (128) NOT NULL,
    [UserName]        NVARCHAR (MAX) NULL,
    [PasswordHash]    NVARCHAR (MAX) NULL,
    [SecurityStamp]   NVARCHAR (MAX) NULL,
    [EmailConfirmed]        BIT            NOT NULL,
    [PhoneNumber]           NVARCHAR (MAX) NULL,
    [PhoneNumberConfirmed]  BIT            NOT NULL,
    [TwoFactorEnabled]      BIT            NOT NULL,
    [LockoutEndDateUtc]     DATETIME       NULL,
    [LockoutEnabled]        BIT            NOT NULL,
```

Below is how the information in the SQL membership tables are mapped to the new Identity system.

aspnet_Roles --> AspNetRoles

asp_netUsers and asp_netMembership --> AspNetUsers

aspnet_UserInRoles --> AspNetUserRoles

As explained in the above section, the AspNetUserClaims and AspNetUserLogins tables are empty. The 'Discriminator' field in the AspNetUser table should match the model class name which is defined as a next step. Also the PasswordHash column is in the form 'encrypted password |password salt|password format'. This enables you to use special SQL membership crypto logic so that you can reuse old passwords. That is explained in later in the article.

Creating models and membership pages

As mentioned earlier, the Identity feature uses Entity Framework to talk to the database for storing account information by default. To work with existing data in the table, we need to create model classes which map back to the tables and hook them up in the Identity system. As part of the Identity contract, the model classes should either implement the interfaces defined in the Identity.Core dll or can extend the existing implementation of these interfaces available in Microsoft.AspNet.Identity.EntityFramework.

In our sample, the AspNetRoles, AspNetUserClaims, AspNetLogins and AspNetUserRole tables have columns that are similar to the existing implementation of the Identity system. Hence we can reuse the existing classes to map to these tables. The AspNetUser table has some additional columns which are used to store additional information from the SQL membership tables. This can be mapped by creating a model class that extend the existing implementation of 'IdentityUser' and add the additional properties.

1. Create a Models folder in the project and add a class User. The name of the class should match the data added in the 'Discriminator' column of 'AspnetUsers' table.

The User class should extend the IdentityUser class found in the *Microsoft.AspNet.Identity.EntityFramework* dll. Declare the properties in class that map back to the AspNetUser columns. The properties ID, Username, PasswordHash and SecurityStamp are defined in the IdentityUser and so are omitted. Below is the code for the User class that has all the properties

```
public class User : IdentityUser
{
    public User()
    {
        CreateDate = DateTime.Now;
        IsApproved = false;
        LastLoginDate = DateTime.Now;
        LastActivityDate = DateTime.Now;
        LastPasswordChangedDate = DateTime.Now;
        LastLockoutDate = DateTime.Parse("1/1/1754");
        FailedPasswordAnswerAttemptWindowStart = DateTime.Parse("1/1/1754");
        FailedPasswordAttemptWindowStart = DateTime.Parse("1/1/1754");
    }

    public System.Guid ApplicationId { get; set; }
    public string MobileAlias { get; set; }
    public bool IsAnonymous { get; set; }
    public System.DateTime LastActivityDate { get; set; }
    public string MobilePIN { get; set; }
    public string LoweredEmail { get; set; }
    public string LoweredUserName { get; set; }
    public string PasswordQuestion { get; set; }
    public string PasswordAnswer { get; set; }
    public bool IsApproved { get; set; }
    public bool IsLockedOut { get; set; }
    public System.DateTime CreateDate { get; set; }
    public System.DateTime LastLoginDate { get; set; }
    public System.DateTime LastPasswordChangedDate { get; set; }
    public System.DateTime LastLockoutDate { get; set; }
    public int FailedPasswordAttemptCount { get; set; }
    public System.DateTime FailedPasswordAttemptWindowStart { get; set; }
    public int FailedPasswordAnswerAttemptCount { get; set; }
    public System.DateTime FailedPasswordAnswerAttemptWindowStart { get; set; }
    public string Comment { get; set; }
}
```

2. An Entity Framework DbContext class is required in order to persist data in models back to tables and retrieve data from tables to populate the models. *Microsoft.AspNet.Identity.EntityFramework* dll defines the IdentityDbContext class which interacts with the Identity tables to retrieve and store information. The IdentityDbContext<tuser> takes a 'TUser' class which can be any class that extends the IdentityUser class.

   Create a new class ApplicationDBContext that extends IdentityDbContext under the 'Models' folder, passing in the 'User' class created in step 1

```
public class ApplicationDbContext : IdentityDbContext<User>
{

}
```

3. User management in the new Identity system is done using the UserManager<tuser> class defined in the *Microsoft.AspNet.Identity.EntityFramework* dll. We need to create a custom class that extends UserManager, passing in the 'User' class created in step 1.

   In the Models folder create a new class UserManager that extends UserManager<user>

```
public class UserManager : UserManager<User>
{

}
```

4. The passwords of the users of the application are encrypted and stored in the database. The crypto

algorithm used in SQL membership is different from the one in the new Identity system. To reuse old passwords we need to selectively decrypt passwords when old users log in using the SQL memberships algorithm while using the crypto algorithm in Identity for the new users.

The UserManager class has a property 'PasswordHasher' which stores an instance of a class that implements the 'IPasswordHasher' interface. This is used to encrypt/decrypt passwords during user authentication transactions. In the UserManager class defined in step 3, create a new class SQLPasswordHasher and copy the below code.

```
public class SQLPasswordHasher : PasswordHasher
{
    public override string HashPassword(string password)
    {
        return base.HashPassword(password);
    }

    public override PasswordVerificationResult VerifyHashedPassword(string  hashedPassword, string
providedPassword)
    {
        string[] passwordProperties = hashedPassword.Split('|');
        if (passwordProperties.Length != 3)
        {
            return base.VerifyHashedPassword(hashedPassword, providedPassword);
        }
        else
        {
            string passwordHash = passwordProperties[0];
            int passwordformat = 1;
            string salt = passwordProperties[2];
            if (String.Equals(EncryptPassword(providedPassword, passwordformat, salt), passwordHash,
StringComparison.CurrentCultureIgnoreCase))
            {
                return PasswordVerificationResult.SuccessRehashNeeded;
            }
            else
            {
                return PasswordVerificationResult.Failed;
            }
        }
    }

    //This is copied from the existing SQL providers and is provided only for back-compat.
    private string EncryptPassword(string pass, int passwordFormat, string salt)
    {
        if (passwordFormat == 0) // MembershipPasswordFormat.Clear
            return pass;

        byte[] bIn = Encoding.Unicode.GetBytes(pass);
        byte[] bSalt = Convert.FromBase64String(salt);
        byte[] bRet = null;

        if (passwordFormat == 1)
        { // MembershipPasswordFormat.Hashed
            HashAlgorithm hm = HashAlgorithm.Create("SHA1");
            if (hm is KeyedHashAlgorithm)
            {
                KeyedHashAlgorithm kha = (KeyedHashAlgorithm)hm;
                if (kha.Key.Length == bSalt.Length)
                {
                    kha.Key = bSalt;
                }
                else if (kha.Key.Length < bSalt.Length)
                {
                    byte[] bKey = new byte[kha.Key.Length];
                    Buffer.BlockCopy(bSalt, 0, bKey, 0, bKey.Length);
                    kha.Key = bKey;
```

```
                }
                else
                {
                    byte[] bKey = new byte[kha.Key.Length];
                    for (int iter = 0; iter < bKey.Length; )
                    {
                        int len = Math.Min(bSalt.Length, bKey.Length - iter);
                        Buffer.BlockCopy(bSalt, 0, bKey, iter, len);
                        iter += len;
                    }
                    kha.Key = bKey;
                }
                bRet = kha.ComputeHash(bIn);
            }
            else
            {
                byte[] bAll = new byte[bSalt.Length + bIn.Length];
                Buffer.BlockCopy(bSalt, 0, bAll, 0, bSalt.Length);
                Buffer.BlockCopy(bIn, 0, bAll, bSalt.Length, bIn.Length);
                bRet = hm.ComputeHash(bAll);
            }
        }

        return Convert.ToBase64String(bRet);
    }
```

Resolve the compilation errors by importing the System.Text and System.Security.Cryptography namespaces.

The EncodePassword method encrypts the password according to the default SQL membership crypto implementation. This is taken from the System.Web dll. If the old app used a custom implementation then it should be reflected here. We need to define two other methods *HashPassword* and *VerifyHashedPassword* that use the *EncodePassword* method to hash a given password or verify a plain text password with the one existing in the database.

The SQL membership system used PasswordHash, PasswordSalt and PasswordFormat to hash the password entered by users when they register or change their password. During the migration all the three fields are stored in the PasswordHash column in the AspNetUser table separated by the '|' character. When a user logs in and the password has these fields, we use the SQL membership crypto to check the password; otherwise we use the Identity system's default crypto to verify the password. This way old users would not have to change their passwords once the app is migrated.

5. Declare the constructor for the UserManager class and pass this as the SQLPasswordHasher to the property in the constructor.

```
public UserManager()
            : base(new UserStore<User>(new ApplicationDbContext()))
{
            this.PasswordHasher = new SQLPasswordHasher();
}
```

Create new account management pages

The next step in the migration is to add account management pages that will let a user register and log in. The old account pages from SQL membership use controls that don't work with the new Identity system. To add the new user management pages follow the tutorial at this link https://www.asp.net/identity/overview/getting-started/adding-aspnet-identity-to-an-empty-or-existing-web-forms-project starting from the step 'Adding Web Forms for registering users to your application' since we have already created the project and added the NuGet packages.

We need to make some changes for the sample to work with the project we have here.

- The Register.aspx.cs and Login.aspx.cs code behind classes use the `UserManager` from the Identity packages to create a User. For this example use the UserManager added in the Models folder by following the steps mentioned earlier.
- Use the User class created instead of the IdentityUser in Register.aspx.cs and Login.aspx.cs code behind classes. This hooks in our custom user class into the Identity system.
- The part to create the database can be skipped.
- The developer needs to set the ApplicationId for the new user to match the current application ID. This can be done by querying the ApplicationId for this application before a user object is created in the Register.aspx.cs class and setting it before creating user.

  Example:

  Define a method in Register.aspx.cs page to query the aspnet_Applications table and get the application Id according to application name

  ```
  private Guid GetApplicationID()
  {
      using (SqlConnection connection = new
  SqlConnection(ConfigurationManager.ConnectionStrings["ApplicationServices"].ConnectionString))
      {
          string queryString = "SELECT ApplicationId from aspnet_Applications WHERE ApplicationName =
  '/'"; //Set application name as in database

          SqlCommand command = new SqlCommand(queryString, connection);
          command.Connection.Open();

          var reader = command.ExecuteReader();
          while (reader.Read())
          {
              return reader.GetGuid(0);
          }

          return Guid.NewGuid();
      }
  }
  ```

  Now get set this on the user object

  ```
  var currentApplicationId = GetApplicationID();

  User user = new User() { UserName = Username.Text,
  ApplicationId=currentApplicationId, …};
  ```

Use the old username and password to login an existing user. Use the Register page to create a new user. Also verify that the users are in roles as expected.

Porting to the Identity system helps the user add Open Authentication (OAuth) to the application. Please refer to the sample here which has OAuth enabled.

Next Steps

In this tutorial we showed how to port users from SQL membership to ASP.NET Identity, but we didn't port Profile data. In the next tutorial we'll look into porting Profile data from SQL membership to the new Identity system.

You can leave feedback at the bottom of this article.

Thanks to Tom Dykstra and Rick Anderson for reviewing the article.

Migrating Universal Provider Data for Membership and User Profiles to ASP.NET Identity (C#)

2/20/2020 • 9 minutes to read • Edit Online

by Pranav Rastogi, Rick Anderson, Robert McMurray, Suhas Joshi

This tutorial describes the steps that are necessary to migrate user and role data and user profile data created using Universal Providers of an existing application to the ASP.NET Identity model. The approach mentioned here to migrate user profile data can be used in an application with SQL membership as well.

With the release of Visual Studio 2013, the ASP.NET team introduced a new ASP.NET Identity system, and you can read more about that release here. Following up on the article to migrate web applications from SQL Membership to the new Identity system, this article illustrates the steps to migrate existing applications that follow the Providers model for user and role management to the new Identity model. The focus of this tutorial will be primarily on migrating the user profile data to seamlessly hook it into the new system. Migrating user and role information is similar for SQL membership. The approach followed to migrate profile data can be used in an application with SQL membership as well.

As an example, we will start with a web app created using Visual Studio 2012 which uses the Providers model. We'll then add code for profile management, register a user, add profile data for the users, migrate the database schema, and then change the application to use the Identity system for user and role management. As a test of migration, users created using Universal Providers should be able to log in and new users should be able to register.

> **NOTE**
>
> You can find the complete sample at https://github.com/suhasj/UniversalProviders-Identity-Migrations.

Profile data migration summary

Before starting with the migrations, let us look at the experience of storing profile data in the Providers model. Profile data for application users can be stored in multiple ways, the most common among them being using the inbuilt profile providers shipped along with the Universal Providers. The steps would include

1. Add a class that has properties used to store Profile data.
2. Add a class that extends 'ProfileBase' and implements methods to get the above profile data for the user.
3. Enable using default profile providers in the *web.config* file and define the class declared in step #2 to be used in accessing profile information.

The profile information is stored as serialized xml and binary data in the 'Profiles' table in the database.

After migrating the application to use the new ASP.NET Identity system, the profile information is deserialized and stored as properties on the user class. Each property can then be mapped onto columns in the user table. The advantage here is that the properties can be worked on directly using the user class in addition to not having to serialize/deserialize data information each time when accessing it.

Getting Started

1. Create a new ASP.NET 4.5 Web Forms application in Visual Studio 2012. The current sample uses the Web

Forms template, but you could use MVC Application as well.

2. Create a new folder 'Models' to store profile information

3. As an example, let us store the date of birth, city, height and weight of the user in profile. The height and weight are stored as a custom class called 'PersonalStats'. To store and retrieve the profile, we need a class that extends 'ProfileBase'. Let's create a new class 'AppProfile' to get and store profile information.

```
public class ProfileInfo
{
    public ProfileInfo()
    {
        UserStats = new PersonalStats();
    }
    public DateTime? DateOfBirth { get; set; }
    public PersonalStats UserStats { get; set; }
    public string City { get; set; }
}

public class PersonalStats
{
    public int? Weight { get; set; }
    public int? Height { get; set; }
}

public class AppProfile : ProfileBase
{
    public ProfileInfo ProfileInfo
    {
        get { return (ProfileInfo)GetPropertyValue("ProfileInfo"); }
    }
    public static AppProfile GetProfile()
    {
        return (AppProfile)HttpContext.Current.Profile;
    }
    public static AppProfile GetProfile(string userName)
    {
        return (AppProfile)Create(userName);
    }
}
```

4. Enable profile in the *web.config* file. Enter the class name to be used to store/retrieve user information created in step #3.

```
<profile defaultProvider="DefaultProfileProvider" enabled="true"
    inherits="UniversalProviders_ProfileMigrations.Models.AppProfile">
  <providers>
    .....
  </providers>
</profile>
```

5. Add a web forms page in 'Account' folder to get the profile data from the user and store it. Right click on project and select 'Add new Item'. Add a new webforms page with master page 'AddProfileData.aspx'. Copy the following in the 'MainContent' section:

```
<h2> Add Profile Data for <%# User.Identity.Name %></h2>
<asp:Label Text="" ID="Result" runat="server" />
<div>
    Date of Birth:
    <asp:TextBox runat="server" ID="DateOfBirth"/>
</div>
<div>
    Weight:
    <asp:TextBox runat="server" ID="Weight"/>
</div>
<div>
    Height:
    <asp:TextBox runat="server" ID="Height"/>
</div>
<div>
    City:
    <asp:TextBox runat="server" ID="City"/>
</div>
<div>
    <asp:Button Text="Add Profile" ID="Add" OnClick="Add_Click" runat="server" />
</div>
```

Add the following code in the code behind:

```
protected void Add_Click(object sender, EventArgs e)
{
    AppProfile profile = AppProfile.GetProfile(User.Identity.Name);
    profile.ProfileInfo.DateOfBirth = DateTime.Parse(DateOfBirth.Text);
    profile.ProfileInfo.UserStats.Weight = Int32.Parse(Weight.Text);
    profile.ProfileInfo.UserStats.Height = Int32.Parse(Height.Text);
    profile.ProfileInfo.City = City.Text;
    profile.Save();
}
```

Add the namespace under which AppProfile class is defined to remove the compilation errors.

6. Run the app and create a new user with username '**olduser**'. Navigate to the 'AddProfileData' page and add profile information for the user.

You can verify that the data is stored as serialized xml in the 'Profiles' table using the Server Explorer window. In Visual Studio, from 'View' menu, choose 'Server Explorer'. There should be a data connection for the database defined in the *web.config* file. Clicking on the data connection shows different sub categories. Expand 'Tables' to show the different tables in your database, then right click on 'Profiles' and choose 'Show Table Data' to view the profile data stored in the Profiles table.

Migrating database schema

To make the existing database work with the Identity system, we need to update the schema in the Identity database to support the fields we added to the original database. This can be done using SQL scripts to create new

tables and copy the existing information. In the 'Server Explorer' window, expand the 'DefaultConnection' to display the tables. Right click Tables and select 'New Query'

Paste the SQL script from https://raw.github.com/suhasj/UniversalProviders-Identity-Migrations/master/Migration.txt and run it. If the 'DefaultConnection' is refreshed, we can see that the new tables are added. You can check the data inside the tables to see that the information has been migrated.

Migrating the application to use ASP.NET Identity

1. Install the Nuget packages needed for ASP.NET Identity:

   - Microsoft.AspNet.Identity.EntityFramework
   - Microsoft.AspNet.Identity.Owin
   - Microsoft.Owin.Host.SystemWeb
   - Microsoft.Owin.Security.Facebook
   - Microsoft.Owin.Security.Google
   - Microsoft.Owin.Security.MicrosoftAccount
   - Microsoft.Owin.Security.Twitter

   More information on managing Nuget packages can be found here

2. To work with existing data in the table, we need to create model classes which map back to the tables and hook them up in the Identity system. As part of the Identity contract, the model classes should either implement the interfaces defined in the Identity.Core dll or can extend the existing implementation of these interfaces available in Microsoft.AspNet.Identity.EntityFramework. We will be using the existing classes for role, user logins and user claims. We need to use a custom user for our sample. Right click on the project and create new folder 'IdentityModels'. Add a new 'User' class as shown below:

```
using Microsoft.AspNet.Identity.EntityFramework;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using UniversalProviders_ProfileMigrations.Models;

namespace UniversalProviders_Identity_Migrations
{
    public class User : IdentityUser
    {
        public User()
        {
            CreateDate = DateTime.UtcNow;
            IsApproved = false;
            LastLoginDate = DateTime.UtcNow;
            LastActivityDate = DateTime.UtcNow;
            LastPasswordChangedDate = DateTime.UtcNow;
            Profile = new ProfileInfo();
        }

        public System.Guid ApplicationId { get; set; }
        public bool IsAnonymous { get; set; }
        public System.DateTime? LastActivityDate { get; set; }
        public string Email { get; set; }
        public string PasswordQuestion { get; set; }
        public string PasswordAnswer { get; set; }
        public bool IsApproved { get; set; }
        public bool IsLockedOut { get; set; }
        public System.DateTime? CreateDate { get; set; }
        public System.DateTime? LastLoginDate { get; set; }
        public System.DateTime? LastPasswordChangedDate { get; set; }
        public System.DateTime? LastLockoutDate { get; set; }
        public int FailedPasswordAttemptCount { get; set; }
        public System.DateTime? FailedPasswordAttemptWindowStart { get; set; }
        public int FailedPasswordAnswerAttemptCount { get; set; }
        public System.DateTime? FailedPasswordAnswerAttemptWindowStart { get; set; }
        public string Comment { get; set; }
        public ProfileInfo Profile { get; set; }
    }
}
```

Notice that the 'ProfileInfo' is now a property on the user class. Hence we can use the user class to directly work with profile data.

Copy the files in the **IdentityModels** and **IdentityAccount** folders from the download source (https://github.com/suhasj/UniversalProviders-Identity-Migrations/tree/master/UniversalProviders-Identity-Migrations). These have the remaining model classes and the new pages needed for user and role management using the ASP.NET Identity APIs. The approach used is similar to the SQL Membership and the detailed explanation can be found here.

> Some commands aren't supported if the app uses SQLite as its Identity data store. Due to limitations in the database engine, `Alter` commands throw the following exception:
>
> "System.NotSupportedException: SQLite does not support this migration operation."
>
> As a work around, run Code First migrations on the database to change the tables.

Copying Profile data to the new tables

As mentioned earlier, we need to deserialize the xml data in the Profiles tables and store it in the columns of the AspNetUsers table. The new columns were created in the users table in the previous step so all that is left is to

populate those columns with the necessary data. To do this, we will use a console application which is run once to populate the newly created columns in the users table.

1. Create a new console application in the exiting solution.

2. Install the latest version of the Entity Framework package.

3. Add the web application created above as a reference to the console application. To do this right click on Project, then 'Add References', then Solution, then click on the project and click OK.

4. Copy the below code in the Program.cs class. This logic reads profile data for each user, serializes it as 'ProfileInfo' object and stores it back to the database.

```
public class Program
{
    var dbContext = new ApplicationDbContext();
    foreach (var profile in dbContext.Profiles)
    {
        var stringId = profile.UserId.ToString();
        var user = dbContext.Users.Where(x => x.Id == stringId).FirstOrDefault();
        Console.WriteLine("Adding Profile for user:" + user.UserName);
        var serializer = new XmlSerializer(typeof(ProfileInfo));
        var stringReader = new StringReader(profile.PropertyValueStrings);
        var profileData = serializer.Deserialize(stringReader) as ProfileInfo;
        if (profileData == null)
        {
            Console.WriteLine("Profile data deserialization error for user:" + user.UserName);
        }
        else
        {
            user.Profile = profileData;
        }
    }
    dbContext.SaveChanges();
}
```

   Some of the models used are defined in the 'IdentityModels' folder of the web application project, so you must include the corresponding namespaces.

5. The above code works on the database file in the App_Data folder of the web application project created in the previous steps. To reference that, update the connection string in the app.config file of the console application with the connection string in the web.config of the web application. Also provide the complete physical path in the 'AttachDbFilename' property.

6. Open a command prompt and navigate to the bin folder of the above console application. Run the executable and review the log output as shown in the following image.

7. Open the 'AspNetUsers' table in the Server Explorer and verify the data in the new columns that hold the properties. They should be updated with the corresponding property values.

Verify functionality

Use the newly added membership pages that are implemented using ASP.NET Identity to login a user from the old database. The user should be able to log in using the same credentials. Try the other functionalities like adding OAuth, creating a new user, changing a password, adding roles, add users to roles, etc.

The Profile data for the old user and the new users should be retrieved and stored in the users table. The old table should no longer be referenced.

Conclusion

The article described the process of migrating web applications that used the provider model for membership to ASP.NET Identity. The article additionally outlined migrating profile data for users to be hooked into the Identity system. Please leave comments below for questions and issues encountered when you migrate your app.

Thanks to Rick Anderson and Robert McMurray for reviewing the article.

Microsoft Ajax Content Delivery Network

9/16/2020 • 14 minutes to read • Edit Online

WARNING

Production applications should not take a hard dependency on CDN assets. Applications should test for the CDN asset referenced, and use a fallback asset when the CDN is not available.

The Microsoft Ajax CDN has no SLA above and beyond using an Azure CDN.

Use this GitHub issue to report problems with the Microsoft Ajax CDN.

ASP.NET Web Forms and Ajax Releases on the CDN
ASP.NET MVC Releases on the CDN
ASP.NET SignalR Releases on the CDN

The Microsoft Ajax Content Delivery Network (CDN) hosts popular third party JavaScript libraries such as jQuery and enables you to easily add them to your Web applications. For example, you can start using jQuery which is hosted on this CDN simply by adding a <script> tag to your page that points to ajax.aspnetcdn.com.

By taking advantage of the CDN, you can significantly improve the performance of your Ajax applications. The contents of the CDN are cached on servers located around the world. In addition, the CDN enables browsers to reuse cached third party JavaScript files for web sites that are located in different domains.

The CDN supports SSL (HTTPS) in case you need to serve a web page using the Secure Sockets Layer.

The CDN hosts the following third party script libraries which have been uploaded, and are licensed to you, by the owners of those libraries:

- jQuery (www.jquery.com)
- jQuery UI (www.jqueryui.com)
- jQuery Mobile (www.jquerymobile.com)
- jQuery Validation (https://jqueryvalidation.org/)
- jQuery Cycle (www.malsup.com/jquery/cycle/)
- jQuery DataTables (http://datatables.net/)

The Microsoft Ajax CDN also includes the following libraries which have been uploaded by Microsoft:

- ASP.NET Ajax
- ASP.NET MVC JavaScript Files
- ASP.NET SignalR JavaScript Files

Microsoft does not claim ownership of any third-party libraries hosted on this CDN. The copyright owners of the libraries are licensing these libraries to you. Any rights that you may have to download and use such libraries are granted solely by the respective copyright owners. Because these are not Microsoft libraries, Microsoft provides no warranties or intellectual property rights licenses (including no implied patent rights) for the third party libraries hosted on this CDN.

If you wish to submit your JavaScript library and your library is one of the top JavaScript libraries (as listed on http://trends.builtwith.com) or extensions/plugins to these libraries that are (a) popular; or (b) helpful for use on ASP.NET then please contact AjaxCDNSubmission@Microsoft.com.

ajax.microsoft.com renamed to ajax.aspnetcdn.com

The CDN used to use the microsoft.com domain name and has been changed to use the aspnetcdn.com domain name. This change was made to increase performance because when a browser referenced the microsoft.com domain it would send any cookies from that domain across the wire with each request. By renaming to a domain name other than microsoft.com performance can be increased by as much to 25%. Note ajax.microsoft.com will continue to function but ajax.aspnetcdn.com is recommended.

- Old Format: https://ajax.microsoft.com/ajax/jQuery/jquery-1.8.0.js
- New Format: https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.8.0.js

Visual Studio .vsdoc Support

To use the .vsdoc files properly with Visual Studio 2008 you need to make sure that you have VS 2008 SP1 installed and the hotfix for vsdoc files installed. You can get these from here:

- Download Visual Studio 2008 SP1
- Download .vsdoc hotfix for Visual Studio 2008 SP1

Visual Studio 2010 supports .vsdoc files without any additional patches.

Using ASP.NET Ajax from the CDN

When using ASP.NET 4, you can redirect all requests for ASP.NET framework scripts to the CDN. Retrieving scripts from the CDN instead of your local web server can substantially improve the performance of public ASP.NET websites.

Use the ScriptManager EnableCDN property to redirect all ASP.NET framework script requests to the Microsoft Ajax CDN:

```
<asp:ScriptManager
    ID="ScriptManager1"
    EnableCdn="true"
    Runat="Server" />
```

Using jQuery from the CDN

You can use jQuery scripts hosted on CDN in your Web application by adding the following script element to a page:

```
<script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-1.9.0.js"></script>
```

The CDN also includes the minified version of the jQuery script, which you can get using the following element:

```
<script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-1.9.0.min.js"></script>
```

To allow your page to fallback to loading jQuery from a local path on your own website if the CDN happens to be unavailable, add the following element immediately after the element referencing the CDN:

```
<script>
  // Fallback to loading jQuery from a local path if the CDN is unavailable
  (window.jQuery || document.write('<script src="/scripts/jquery-1.9.0.min.js"><\/script>'));
</script>
```

The following sample page uses the CDN version of the jQuery library (with fallback to a local copy) to display the contents of a div element when a button is clicked.

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>jQuery from Microsoft AJAX CDN</title>
</head>
<body>
    <button id="btn">Show Message</button>

    <div id="message" style="display:none">
        <h1>Hello from jQuery!</h1>
    </div>

    <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-1.9.0.min.js"></script>
    <script>
        // Fallback to loading jQuery from a local path if the CDN is unavailable
        (window.jQuery || document.write('<script src="/scripts/jquery-1.9.0.min.js"><\/script>'));
    </script>
    <script>
        function domReady() {
            $('#btn').click( showMessage );
        }

        function showMessage() {
            $('#message').fadeIn('slow');
        }

        $( domReady );
    </script>
</body>
</html>
```

You can learn more about jQuery and download a local copy of jQuery by visiting the jQuery Web site.

Using jQuery UI from the CDN

The CDN also hosts the jQuery UI library. The jQuery UI library includes a rich set of widgets and effects that you can use in your ASP.NET applications. For example, the following page illustrates how you can use the jQuery UI Datepicker in the context of an ASP.NET Web Forms application to display a pop-up calendar:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="WebForm1.aspx.cs"
Inherits="TestjQueryUICDN.WebForm1" %>
<!DOCTYPE html >
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Using jQuery UI from the CDN</title>
    <link rel="Stylesheet" href="https://ajax.aspnetcdn.com/ajax/jquery.ui/1.8.10/themes/redmond/jquery-
ui.css" />
</head>
<body>
    <form id="form1" runat="server">
    <div>
        <asp:TextBox ID="txtStartDate" ClientIDMode="Static" runat="server" />
    </div>
    </form>
    <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-1.8.0.js"></script>
    <script src="https://ajax.aspnetcdn.com/ajax/jquery.ui/1.8.22/jquery-ui.js"></script>
    <script>
        $("#txtStartDate").datepicker();
    </script>
</body>
</html>
```

When you move focus to the TextBox using your keyboard, a calendar is displayed:

Notice that you must include three files from the CDN in the code above:

- The jQuery library — The jQuery UI library depends on the jQuery library. You must add the jQuery library to your page before you add the jQuery UI library.
- The jQuery UI library — The jQuery UI library contains all of the jQuery UI effects and widgets such as the

Datepicker widget used in the page above.

- A jQuery UI theme — The jQuery UI supports different themes. The page above includes a link to a CSS file to import the Redmond theme.

All of the standard jQuery UI themes are hosted on the CDN. Visit this page to view thumbnails for each theme.

To learn more about the jQuery UI library, visit the official jQuery UI website.

Third-Party Files on the CDN

The CDN hosts some of the most popular third party JavaScript libraries. Microsoft does not claim ownership of any third-party libraries hosted on this CDN. The copyright owners of the libraries are licensing these libraries to you. Any rights that you may have to download and use such libraries are granted solely by the respective copyright owners. Because these are not Microsoft libraries, Microsoft provides no warranties or intellectual property rights licenses (including no implied patent rights) for the third party libraries hosted on this CDN.

jQuery Releases on the CDN

The following releases of jQuery are hosted on the CDN:

jQuery version 3.5.1

- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.1.js
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.1.min.js
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.1.min.map
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.1.slim.js
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.1.slim.min.js
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.1.slim.min.map

jQuery version 3.5.0

- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.0.js
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.0.min.js
- https://ajax.aspnetcdn.com/ajax/jQuery/jquery-3.5.0.min.map

jQuery Migrate Releases on the CDN

The following releases of jQuery Migrate are hosted on the CDN:

jQuery Migrate version 3.0.0

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-3.0.0.js
- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-3.0.0.min.js

jQuery Migrate version 1.2.1

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.2.1.js
- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.2.1.min.js

jQuery Migrate version 1.2.0

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.2.0.js
- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.2.0.min.js

jQuery Migrate version 1.1.1

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.1.1.js
- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.1.1.min.js

jQuery Migrate version 1.1.0

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.1.0.js
- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.1.0.min.js

jQuery Migrate version 1.0.0

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.0.0.js

- https://ajax.aspnetcdn.com/ajax/jquery.migrate/jquery-migrate-1.0.0.min.js

jQuery UI Releases on the CDN

The following releases of the jQuery UI library are hosted on this CDN. Click each link to see the actual list of files.

- jQuery UI 1.12.1
- jQuery UI 1.12.0
- jQuery UI 1.11.4
- jQuery UI 1.11.3
- jQuery UI 1.11.2
- jQuery UI 1.11.1
- jQuery UI 1.11.0
- jQuery UI 1.10.4
- jQuery UI 1.10.3
- jQuery UI 1.10.2
- jQuery UI 1.10.1
- jQuery UI 1.10.0
- jQuery UI 1.9.2
- jQuery UI 1.9.1
- jQuery UI 1.9.0
- jQuery UI 1.8.24
- jQuery UI 1.8.23
- jQuery UI 1.8.22
- jQuery UI 1.8.21
- jQuery UI 1.8.20
- jQuery UI 1.8.19
- jQuery UI 1.8.18
- jQuery UI 1.8.17
- jQuery UI 1.8.16
- jQuery UI 1.8.15
- jQuery UI 1.8.14
- jQuery UI 1.8.13
- jQuery UI 1.8.12
- jQuery UI 1.8.11
- jQuery UI 1.8.10
- jQuery UI 1.8.9
- jQuery UI 1.8.8
- jQuery UI 1.8.7
- jQuery UI 1.8.6
- jQuery UI 1.8.5

jQuery Validation Releases on the CDN

The following releases of the jQuery Validation plugin are hosted on this CDN. Click each link to see the actual list of files.

- jQuery Validate 1.19.2
- jQuery Validate 1.19.1
- jQuery Validate 1.19.0
- jQuery Validate 1.17.0

- jQuery Validate 1.16.0
- jQuery Validate 1.15.1
- jQuery Validate 1.15.0
- jQuery Validate 1.14.0
- jQuery Validate 1.13.1
- jQuery Validate 1.13.0
- jQuery Validate 1.12.0
- jQuery Validate 1.11.1
- jQuery Validate 1.11.0
- jQuery Validate 1.10.0
- jQuery Validate 1.9
- jQuery Validate 1.8.1
- jQuery Validate 1.8
- jQuery Validate 1.7
- jQuery Validate 1.6
- jQuery Validate 1.5.5

jQuery Mobile Releases on the CDN

The following releases of the jQuery Mobile library are hosted on this CDN. Click each link to see the actual list of files.

- jQuery Mobile 1.4.5
- jQuery Mobile 1.4.2
- jQuery Mobile 1.4.1
- jQuery Mobile 1.4.0
- jQuery Mobile 1.3.2
- jQuery Mobile 1.3.1
- jQuery Mobile 1.3.0
- jQuery Mobile 1.2.0
- jQuery Mobile 1.1.2
- jQuery Mobile 1.1.1
- jQuery Mobile 1.1.0
- jQuery Mobile 1.1.0 RC 2
- jQuery Mobile 1.0.1
- jQuery Mobile 1.0
- jQuery Mobile 1.0 RC 2
- jQuery Mobile 1.0 RC 1
- jQuery Mobile 1.0 beta 3

jQuery Templates Releases on the CDN

The following releases of the jQuery Templates plugin are hosted on this CDN. Click each link to see the actual list of files.

- jQuery Templates Beta 1

jQuery Cycle Releases on the CDN

The following releases of the jQuery Cycle plugin are hosted on this CDN. Click each link to see the actual list of files.

- jQuery Cycle 2.99

- jQuery Cycle 2.94
- jQuery Cycle 2.88

jQuery DataTables Releases on the CDN

The following releases of the jQuery DataTables plugin are hosted on this CDN. Click each link to see the actual list of files.

- jQuery DataTables 1.10.5
- jQuery DataTables 1.10.4
- jQuery DataTables 1.9.4
- jQuery DataTables 1.9.3
- jQuery DataTables 1.9.2
- jQuery DataTables 1.9.1
- jQuery DataTables 1.9.0
- jQuery DataTables 1.8.2

Modernizr Releases on the CDN

The following releases of Modernizr are hosted on the CDN:

- https://ajax.aspnetcdn.com/ajax/modernizr/modernizr-3.5.0.js
- https://ajax.aspnetcdn.com/ajax/modernizr/modernizr-2.8.3.js

- jQuery Cycle 2.99
- jQuery Cycle 2.94
- jQuery Cycle 2.88

jQuery Cycle 2.99

2/20/2020 • 2 minutes to read • Edit Online

The following jQuery Cycle files are hosted on this CDN:

- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.99/jquery.cycle.all.js — The full version of the jQuery Cycle plugin. Includes more than two dozen special effects and all of the options.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.99/jquery.cycle.all.min.js — The minified version of the file above. Use this version for production applications to improve your website performance.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.99/jquery.cycle.js — This version of the jQuery Cycle plugin is smaller and contains only the "fade" transition effect.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.99/jquery.cycle.min.js — The minified version of the file above. Use this version for production applications to improve your website performance.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.99/jquery.cycle.lite.js — An even smaller version of the jQuery Cycle plugin that contains only the "fade" transition without all of the options.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.99/jquery.cycle.lite.min.js — The minified version of the file above. Use this version for production applications to improve your website performance.

jQuery Cycle 2.94

2/20/2020 • 2 minutes to read • Edit Online

The following jQuery Cycle files are hosted on this CDN:

- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.94/jquery.cycle.all.js — The full version of the jQuery Cycle plugin. Includes all the more than two dozen special effects and all of the options.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.94/jquery.cycle.all.min.js — The minified version of the file above. Use this version for production applications to improve your website performance.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.94/jquery.cycle.js — This version of the jQuery Cycle plugin is smaller and contains only the "fade" transition effect.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.94/jquery.cycle.min.js — The minified version of the file above. Use this version for production applications to improve your website performance.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.94/jquery.cycle.lite.js — An even smaller version of the jQuery Cycle plugin that contains only the "fade" transition without all of the options.
- https://ajax.aspnetcdn.com/ajax/jquery.cycle/2.94/jquery.cycle.lite.min.js — The minified version of the file above. Use this version for production applications to improve your website performance.

jQuery Cycle 2.88

2/20/2020 • 2 minutes to read • Edit Online

The following jQuery Cycle files are hosted on this CDN:

What not to do in ASP.NET, and what to do instead

2/20/2020 • 11 minutes to read • Edit Online

This topic describes several common mistakes people make within ASP.NET web projects. It provides recommendations for what you should do to avoid these common mistakes. It is based on a presentation by **Damian Edwards** at Norwegian Developers Conference.

Disclaimer

This topic is not intended as a complete guide to ensure your application is secure and efficient. You still need to follow best practices for security and performance that are not outlined in this topic. It only suggests how to avoid common mistakes related to .NET classes and processes.

Overview

This topic contains the following sections:

- Standards Compliance
  - Control Adapters
  - Style Properties on Controls
  - Page and Control Callbacks
  - Browser Capability Detection
- Security
  - Request Validation
  - Cookieless Forms Authentication and Session
  - EnableViewStateMac
  - Medium Trust
  - <appSettings>
  - UrlPathEncode
- Reliability and Performance
  - PreSendRequestHeaders and PreSendRequestContent
  - Asynchronous Page Events with Web Forms
  - Fire-and-Forget Work
  - Request Entity Body
  - Response.Redirect and Response.End
  - EnableViewState and ViewStateMode
  - SqlMembershipProvider
  - Long Running Requests (>110 seconds)

Standards Compliance

Control adapters

Recommendation: Stop using control adapters for adaptive rendering, and instead use CSS media queries and standards-compliant HTML.

Controls Adapters were introduced in .NET 2.0 to render presentation code that was customized for different

devices and environments. Now, this adaptive rendering can be accomplished with CSS and HTML. You should stop using Control Adapters and convert any existing adapters to CSS and HTML.

For more information, see Media Queries and How To: Add Mobile Pages to Your ASP.NET Web Forms / MVC Application.

Style properties on controls

Recommendation: Stop setting style values in the control markup, and instead set formatting values in CSS stylesheets.

Web server controls contain dozens of properties which can be used to set in-line style properties. For example, the ForeColor property sets the color of the text for a control. You can accomplish this same effect more efficiently through CSS stylesheets. Stylesheets enable you to centralize style values and avoid setting these values throughout your application.

The following example shows a CSS class the sets text to red.

```
.CautionRow {
    color: red;
}
```

The next example shows how to dynamically apply the CSS class.

```
protected void CustomersGridView_RowDataBound(object sender, GridViewRowEventArgs e)
{
    if (e.Row.Cells[2].Text == "Unconfirmed")
    {
        e.Row.CssClass = "CautionRow";
    }
}
```

Page and control callbacks

Recommendation: Stop using page and control callbacks, and instead use any of the following: AJAX, UpdatePanel, MVC action methods, Web API, or SignalR.

In earlier versions of ASP.NET, Page and Control callback methods enabled you to update part of the web page without refreshing an entire page. You can now accomplish partial-page updates through AJAX, UpdatePanel, MVC, Web API or SignalR. You should stop using callback methods because they can cause issues with friendly URLs and routing. By default, controls do not enable callback methods, but if you enabled this feature in a control, you should disable it.

Browser capability detection

Recommendation: Stop using static browser capability detection, and instead use dynamic feature detection.

In earlier versions of ASP.NET, the supported features for each browser were stored in an XML file. Detecting feature support through a static lookup is not the best approach. Now, you can dynamically detect a browser's supported features by using a feature detection framework, such as Modernizr. Feature detection determines support by attempting to use a method or property and then checking to see if the browser produced the desired result. By default, Modernizr is included in the Web application templates.

Security

Request validation

Recommendation: Validate user input, and encode output from users.

Request validation is a feature of ASP.NET that inspects each request and stops the request if a perceived threat is

found. Do not depend on request validation for securing your application against cross-site scripting attacks. Instead, validate all input from users and encode the output. In some limited cases, you can use regular expressions to validate the input, but in more complicated cases you should validate user input by using .NET classes that determine if the value matches allowed values.

The following example shows how to use a static method in the Uri class to determine whether the Uri provided by a user is valid.

```
var isValidUri = Uri.IsWellFormedUriString(passedUri, UriKind.Absolute);
```

However, to sufficiently verify the Uri, you should also check to make sure it specifies `http` or `https`. The following example uses instance methods to verify that the Uri is valid.

```
var uriToVerify = new Uri(passedUri);
var isValidUri = uriToVerify.IsWellFormedOriginalString();
var isValidScheme = uriToVerify.Scheme == "http" || uriToVerify.Scheme == "https";
```

Before rendering user input as HTML or including user input in a SQL query, encode the values to ensure malicious code is not included.

You can HTML encode the value in markup with the <%: %> syntax, as shown below.

```
<span><%: userInput %></span>
```

Or, in Razor syntax, you can HTML encode with @, as shown below.

```
<span>@userInput</span>
```

The next example shows how to HTML encode a value in code-behind.

```
var encodedInput = Server.HtmlEncode(userInput);
```

To safely encode a value for SQL commands, use command parameters such as the SqlParameter.

Cookieless forms authentication and session

Recommendation: Require cookies.

Passing authentication information in the query string is not secure. Therefore, require cookies when your application includes authentication. If your cookie stores sensitive information, consider requiring SSL for the cookie.

The following example shows how to specify in the Web.config file that Forms Authentication requires a cookie that is transmitted over SSL.

```
<authentication mode="Forms">
  <forms loginUrl="member_login.aspx"
    cookieless="UseCookies"
    requireSSL="true"
    path="/MyApplication" />
</authentication>
```

EnableViewStateMac

Recommendation: Never set to false.

By default, EnableViewStateMac is set to true. Even if your application is not using view state, do not set EnableViewStateMac to false. Setting this value to false will make your application vulnerable to cross-site scripting.

Starting with ASP.NET 4.5.2, the runtime enforces **EnableViewStateMac=true**. Even if you set it to false, the runtime ignores this value and proceeds with the value set to true. For more information, see ASP.NET 4.5.2 and EnableViewStateMac.

The following example shows how to set EnableViewStateMac to true. You do not need to actually set this value to true because it is true by default. However, if you have set it to false on any page in your application, you must immediately correct this value.

```
<%@ Page language="C#" EnableViewStateMac="true" %>
```

Medium trust

Recommendation: Do not depend on Medium Trust (or any other trust level) as a security boundary.

Partial trust does not adequately protect your application and should not be used. Instead, use Full Trust, and isolate untrusted applications in separate application pools. Also, run each application pool under a unique identity. For more information, see ASP.NET Partial Trust does not guarantee application isolation.

<appSettings>

Recommendation: Do not disable security settings in <appSettings> element.

The appSettings element contains many values which are required for security updates. You should not change or disable these values. If you must disable these values when deploying an update, immediately re-enable after completing deployment.

For details, see ASP.NET appSettings Element.

UrlPathEncode

Recommendation: Use UrlEncode instead.

The UrlPathEncode method was added to the .NET Framework to resolve a very specific browser compatibility problem. It does not adequately encode a URL, and does not protect your application from cross-site scripting. You should never use it in your application. Instead, use UrlEncode.

The following example shows how to pass an encoded URL as a query string parameter for a hyperlink control.

```
string destinationURL = "http://www.contoso.com/default.aspx?user=test";
NextPage.NavigateUrl = "~/Finish?url=" + Server.UrlEncode(destinationURL);
```

Reliability and performance

PreSendRequestHeaders and PreSendRequestContent

Recommendation: Do not use these events with managed modules. Instead, write a native IIS module to perform the required task. See Creating Native-Code HTTP Modules.

You can use the PreSendRequestHeaders and PreSendRequestContent events with native IIS modules.

> **WARNING**
> Do not use `PreSendRequestHeaders` and `PreSendRequestContent` with managed modules that implement `IHttpModule`. Setting these properties can cause issues with asynchronous requests. The combination of Application Requested Routing (ARR) and websockets might lead to access violation exceptions that can cause w3wp to crash. For example, iiscore!W3_CONTEXT_BASE::GetIsLastNotification+68 in iiscore.dll has caused an access violation exception (0xC0000005).

Asynchronous page events with web forms

Recommendation: In Web Forms, avoid writing async void methods for Page lifecycle events, and instead use Page.RegisterAsyncTask for asynchronous code.

When you mark a page event with **async** and **void**, you cannot determine when the asynchronous code has finished. Instead, use Page.RegisterAsyncTask to run the asynchronous code in a way that enables you to track its completion.

The following example shows a button click handler that contains asynchronous code. This example includes reading a string value asynchronously, which is provided only as a simplified example of an asynchronous task and not as a recommended practice.

```
protected void StartAsync_Click(object sender, EventArgs e)
{
    Page.RegisterAsyncTask(new PageAsyncTask(async() =>
    {
        string stringToRead = "Long text value";

        using (StringReader reader = new StringReader(stringToRead))
        {
            string readText = await reader.ReadToEndAsync();
            Result.Text = readText;
        }
    }));
}
```

If you are using asynchronous Tasks, set the Http runtime target framework to 4.5 (or later) in the Web.config file. Setting the target framework to 4.5 turns on the new synchronization context that was added in .NET 4.5. This value is set by default in new projects in Visual Studio, but is not be set if you are working with an existing project.

```
<system.web>
    <httpRuntime TargetFramework="4.5" />
</system.web>
```

Fire-and-forget work

Recommendation: When handling a request within ASP.NET, avoid launching fire-and-forget work (such calling the ThreadPool.QueueUserWorkItem method or creating a timer that repeatedly calls a delegate).

If your application has fire-and-forget work that runs within ASP.NET, your application can get out of sync. At any time, the app domain can be destroyed which means your ongoing process may no longer match the current state of the application.

You should move this type of work outside of ASP.NET. You can use a Web Jobs, Windows Service or a Worker role in Azure to perform ongoing work, and run that code from another process.

If you must perform this work within ASP.NET, you can add the Nuget package called WebBackgrounder to run the code.

Request entity body

Recommendation: Avoid reading Request.Form or Request.InputStream before the handler's execute event.

The earliest you should read from Request.Form or Request.InputStream is during the handler's execute event. In MVC, the Controller is the handler and the execute event is when the action method runs. In Web Forms, the Page is the handler and the execute event is when the Page.Init event fires. If you read the request entity body earlier than the execute event, you interfere with the processing of the request.

If you need to read the request entity body before the execute event, use either Request.GetBufferlessInputStream or Request.GetBufferedInputStream. When you use GetBufferlessInputStream, you get the raw stream from the request, and assume responsibility for processing the entire request. After calling GetBufferlessInputStream, Request.Form and Request.InputStream are not available because they have not been populated by ASP.NET. When you use GetBufferedInputStream, you get a copy of the stream from the request. Request.Form and Request.InputStream are still available later in the request because ASP.NET populates the other copy.

Response.Redirect and Response.End

Recommendation: Be aware of differences in how thread is handled after calling Response.Redirect(String).

The Response.Redirect(String) method calls the Response.End method. In a synchronous process, calling Request.Redirect causes the current thread to immediately abort. However, in an asynchronous process, calling Response.Redirect does not abort the current thread, so code execution continues for the request. In an asynchronous process, you must return the Task from the method to stop the code execution.

In an MVC project, you should not call Response.Redirect. Instead, return a RedirectResult.

EnableViewState and ViewStateMode

Recommendation: Use ViewStateMode, instead of EnableViewState, to provide granular control over which controls use view state.

When you set EnableViewState to false in the Page directive, view state is disabled for all controls within the page and cannot be enabled. If you want to enable view state for only certain controls in your page, set ViewStateMode to Disabled for the Page.

```
<%@ Page ViewStateMode="Disabled" . . . %>
```

Then, set ViewStateMode to Enabled on only the controls that actually need view state.

```
<asp:GridView ViewStateMode="Enabled" runat="server">
```

By enabling view state for only the controls that need it, you can shrink the size of the view state for your web pages.

SqlMembershipProvider

Recommendation: Use Universal Providers.

In the current project templates, SqlMembershipProvider has been replaced by ASP.NET Universal Providers, which is available as a NuGet package. If you are using SqlMembershipProvider in a project that was built with an earlier version of the templates, you should switch to Universal Providers. The Universal Providers work with all databases that are supported by Entity Framework.

For more information, see Introducing ASP.NET Universal Providers.

Long-running requests (>110 seconds)

Recommendation: Use WebSockets or SignalR for connected clients, and use asynchronous I/O operations.

Long-running requests can cause unpredictable results and poor performance in your web application. The default timeout setting for a request is 110 seconds. If you are using session state with a long-running request, ASP.NET

will release the lock on the Session object after 110 seconds. However, your application might be in the middle of an operation on the Session object when the lock is released, and the operation might not complete successfully. If a second request from the user is blocked while the first request is running, the second request might access the Session object in an inconsistent state.

If your application includes blocking (or synchronous) I/O operations, the application will be unresponsive.

To improve performance, use the asynchronous I/O operations in the .NET Framework. Also, use WebSockets or SignalR for connecting clients to the server. These features are designed to efficiently handle long-running requests.

Download Fix It Project or Download E-book

> This e-book walks you through a patterns-based approach to building real-world cloud solutions. The patterns apply to the development process as well as to architecture and coding practices.
>
> The content is based on a presentation developed by Scott Guthrie and delivered by him at the Norwegian Developers Conference (NDC) in June of 2013 (part 1, part 2), and at Microsoft Tech Ed Australia in September, 2013 (part 1, part 2). Many others updated and augmented the content while transitioning it from video to written form.

Intended Audience

Developers who are curious about developing for the cloud, considering a move to the cloud, or are new to cloud development will find here a concise overview of the most important concepts and practices they need to know. The concepts are illustrated with concrete examples, and each chapter links to other resources for more in-depth information. The examples and the links to additional resources are for Microsoft frameworks and services, but the principles illustrated apply to other web development frameworks and cloud environments as well.

Developers who are already developing for the cloud may find ideas here that will help make them more successful. Each chapter in the series can be read independently, so you can pick and choose topics that you're interested in.

Anyone who watched Scott Guthrie's *Building Real World Cloud Apps with Azure* presentation and wants more details and updated information will find that here.

Cloud development patterns

This e-book explains thirteen recommended patterns for cloud development. "Pattern" is used here in a broad sense to mean a recommended way to do things: how best to go about developing, designing, and coding cloud apps. These are key patterns which will help you "fall into the pit of success" if you follow them.

- Automate everything.
  - Use scripts to maximize efficiency and minimize errors in repetitive processes.
  - Demo: Azure management scripts.
- Source control.
  - Set up branching structure in source control to facilitate DevOps workflow.
  - Demo: add scripts to source control.
  - Demo: keep sensitive data out of source control.
  - Demo: use Git in Visual Studio.
- Continuous integration and delivery.
  - Automate build and deployment with each source control check-in.
- Web development best practices.

- Keep web tier stateless.
- Demo: scaling and auto-scaling in Web Apps in Azure App Service.
- Avoid session state.
- Use a CDN with a fallback when the CDN is unavailable.
- Use asynchronous programming model.
- Demo: async in ASP.NET MVC and Entity Framework.

- Single sign-on.
  - Introduction to Azure Active Directory.
  - Demo: create an ASP.NET app that uses Azure Active Directory.
- Data storage options.
  - Types of data stores.
  - How to choose the right data store.
  - Demo: Azure SQL Database.
- Data partitioning strategies.
  - Partition data vertically, horizontally, or both to facilitate scaling a relational database.
- Unstructured blob storage.
  - Store files in the cloud by using the blob service.
  - Demo: using blob storage in the Fix It app.
- Design to survive failures.
  - Types of failures.
  - Failure Scope.
  - Understanding SLAs.
- Monitoring and telemetry.
  - Why you should both buy a telemetry app and write your own code to instrument your app.
  - Demo: New Relic for Azure
  - Demo: logging code in the Fix It app.
  - Demo: dependency injection in the Fix It app.
  - Demo: built-in logging support in Azure.
- Transient fault handling.
  - Use smart retry/back-off logic to mitigate the effect of transient failures.
  - Demo: retry/back-off in Entity Framework 6.
- Distributed caching.
  - Improve scalability and reduce database transaction costs by using distributed caching.
- Queue-centric work pattern.
  - Enable high availability and improve scalability by loosely coupling web and worker tiers.
  - Demo: Azure storage queues in the Fix It app.
- More cloud app patterns and guidance.
- Appendix: The Fix It Sample Application
  - Known Issues
  - Best Practices
  - How to download, build, run, and deploy.

These patterns apply to all cloud environments, but we'll illustrate them by using examples based on Microsoft technologies and services, such as Visual Studio, Team Foundation Service, ASP.NET, and Azure.

This remainder of this chapter introduces the Fix It sample application and the Web Apps in Azure App Service cloud environment that the Fix It app runs in.

The Fix it sample application

Most of the screen shots and code examples shown in this e-book are based on the Fix It app originally developed by Scott Guthrie to demonstrate recommended cloud app development patterns and practices.

The sample app is a simple work item ticketing system. When you need something fixed, you create a ticket and assign it to someone, and others can log in and see the tickets assigned to them and mark tickets as completed when the work is done.

It's a standard Visual Studio web project. It is built on ASP.NET MVC and uses a SQL Server database. It can run locally in IIS Express and can be deployed to a Azure Web Site to run in the cloud. You can log in using forms authentication and a local database or by using a social provider such as Google. (Later we'll also show how to log in with an Active Directory organizational account.)

Once you're logged in you can create a ticket, assign it to someone, and upload a picture of what you want to get fixed.

You can track the progress of work items you created, see tickets assigned to you, view ticket details, and mark items as completed.

This is a very simple app from a feature perspective, but you'll see how to build it so that it can scale to millions of users and will be resilient to things like database failures and connection terminations. You'll also see how to create an automated and agile development workflow, which enables you to start simple and make the app better and better by iterating the development cycle efficiently and quickly.

Web Apps in Azure App Service

The cloud environment used for the Fix It application is a service of Azure that we call Web Sites. This service is a way that you can host your own web app in Azure without having to create VMs and keep them updated, install and configure IIS, etc. We host your site on our VMs and automatically provide backup and recovery and other services for you. The Web Sites service works with ASP.NET, Node.js, PHP, and Python. It enables you to deploy very quickly using Visual Studio, Web Deploy, FTP, Git, or TFS. It's usually just a few seconds between the time you start a deployment and the time your update is available over the Internet. It's all free to get started, and you can scale up as your traffic grows.

Behind the scenes, Web Apps in Azure App Service provides a lot of architectural components and features that you'd have to build yourself if you were going to host a web site using IIS on your own VMs. One component is a deployment end point that automatically configures IIS and installs your application on as many VMs as you want to run your site on.

When a user hits the web site, they don't hit the IIS VMs directly, they go through Application Request Routing (ARR) load balancers. You can use these with your own servers, but the advantage here is that they're set up for you automatically. They use a smart heuristic that takes into account factors such as session affinity, queue depth in IIS, and CPU usage on each machine to direct traffic to the VMs that host your web site.

If a machine goes down, Azure automatically pulls it from the rotation, spins up a new VM instance, and starts directing traffic to the new instance -- all with no down time for your application.

All of this takes place automatically. All you need to do is create a web site and deploy your application to it, using Windows PowerShell, Visual Studio, or the Azure management portal.

For a quick and easy step-by-step tutorial that shows how to create a web application in Visual Studio and deploy it to a Azure Web Site, see Get started with Azure and ASP.NET.

Summary

This introduction has provided a list of topics the book will cover, screenshots of the sample application, and a brief overview of the Web Apps in Azure App Service cloud environment. One of the great advantages of developing apps in and for the cloud is that it's easy to automate repetitive development tasks such as creating a test environment and deploying your code to it. How to do that is the subject of the next chapter.

Resources

For more information about the topics covered in this chapter, see the following resources.

Documentation:

- Web Apps in Azure App Service. Portal page for Azure documentation about Web Apps.
- Web Apps, Cloud Services, and VMs: When to use which? WAWS as shown in this chapter is just one of three ways you can run web apps in Azure. This article explains the differences between the three ways and gives guidance on how to choose which one is right for your scenario. Like Web Sites, Cloud Services is a PaaS feature of Azure. VMs are an IaaS feature. For an explanation of PaaS versus IaaS, see the Data Options chapter.

Automate Everything (Building Real-World Cloud Apps with Azure)

2/20/2020 • 14 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For an introduction to the e-book, see the first chapter.

The first three patterns we'll look at actually apply to any software development project, but especially to cloud projects. This pattern is about automating development tasks. It's an important topic because manual processes are slow and error-prone; automating as many of them as possible helps set up a fast, reliable, and agile workflow. It's uniquely important for cloud development because you can easily automate many tasks that are difficult or impossible to automate in an on-premises environment. For example, you can set up whole test environments including new web server and back-end VMs, databases, blob storage (file storage), queues, etc.

DevOps Workflow

Increasingly you hear the term "DevOps." The term developed out of a recognition that you have to integrate development and operations tasks in order to develop software efficiently. The kind of workflow you want to enable is one in which you can develop an app, deploy it, learn from production usage of it, change it in response to what you've learned, and repeat the cycle quickly and reliably.

Some successful cloud development teams deploy multiple times a day to a live environment. The Azure team used to deploy a major update every 2-3 months, but now it releases minor updates every 2-3 days and major releases every 2-3 weeks. Getting into that cadence really helps you be responsive to customer feedback.

In order to do that, you have to enable a development and deployment cycle that is repeatable, reliable, predictable, and has low cycle time.

In other words, the period of time between when you have an idea for a feature and when the customers are using it and providing feedback must be as short as possible. The first three patterns – automate everything,

source control, and continuous integration and delivery -- are all about best practices that we recommend in order to enable that kind of process.

Azure management scripts

In the introduction to this e-book, you saw the web-based console, the Azure Management Portal. The management portal enables you to monitor and manage all of the resources that you have deployed on Azure. It's an easy way to create and delete services such as web apps and VMs, configure those services, monitor service operation, and so forth. It's a great tool, but using it is a manual process. If you're going to develop a production application of any size, and especially in a team environment, we recommend that you go through the portal UI in order to learn and explore Azure, and then automate the processes that you'll be doing repetitively.

Nearly everything that you can do manually in the management portal or from Visual Studio can also be done by calling the REST management API. You can write scripts using Windows PowerShell, or you can use an open source framework such as Chef or Puppet. You can also use the Bash command-line tool in a Mac or Linux environment. Azure has scripting APIs for all those different environments, and it has a .NET management API in case you want to write code instead of script.

For the Fix It app we've created some Windows PowerShell scripts that automate the processes of creating a test environment and deploying the project to that environment, and we'll review some of the contents of those scripts.

Environment creation script

The first script we'll look at is named *New-AzureWebsiteEnv.ps1*. It creates an Azure environment that you can deploy the Fix It app to for testing. The main tasks that this script performs are the following:

- Create a web app.
- Create a storage account. (Required for blobs and queues, as you'll see in later chapters.)
- Create a SQL Database server and two databases: an application database, and a membership database.
- Store settings in Azure that the app will use to access the storage account and databases.
- Create settings files that will be used to automate deployment.

Run the script

> **NOTE**
> This part of the chapter shows examples of scripts and the commands that you enter in order to run them. This a demo and doesn't provide everything you need to know in order to run the scripts. For step-by-step how-to-do-it instructions, see Appendix: The Fix It Sample Application.

To run a PowerShell script that manages Azure services you have to install the Azure PowerShell console and configure it to work with your Azure subscription. Once you're set up, you can run the Fix It environment creation script with a command like this one:

```
.\New-AzureWebsiteEnv.ps1 -Name <websitename> -SqlDatabasePassword <password>
```

The `Name` parameter specifies the name to be used when creating the database and storage accounts, and the `SqlDatabasePassword` parameter specifies the password for the admin account that will be created for SQL Database. There are other parameters you can use that we'll look at later.

```

PS C:\MyFixIt\Automation>
```

After the script finishes you can see in the management portal what was created. You'll find two databases:

sql databases

DATABASES SERVERS

NAME	STATUS	LOCATION	SUBSCRIPTION	SERVER	EDITION	MAX SIZE
appdb	Online	West US	Windows Azure...	m9qcm7sjzx	Web	1 GB
memberdb	Online	West US	Windows Azure...	m9qcm7sjzx	Web	1 GB

A storage account:

storage

NAME	STATUS	LOCATION	SUBSCRIPTION
fixitdemostorage	Online	West US	Windows Azure MSDN

And a web app:

On the **Configure** tab for the web app, you can see that it has the storage account settings and SQL database connection strings set up for the Fix It app.

The *Automation* folder now also contains a *<websitename>.pubxml* file. This file stores settings that MSBuild will use to deploy the application to the Azure environment that was just created. For example:

```
<?xml version="1.0" encoding="utf-8"?>
<Project ToolsVersion="4.0" xmlns="http://schemas.microsoft.com/developer/msbuild/2003">
  <PropertyGroup>
    <WebPublishMethod>MSDeploy</WebPublishMethod>
    <SiteUrlToLaunchAfterPublish>http://fixitdemo.azurewebsites.net</SiteUrlToLaunchAfterPublish>
    <ExcludeApp_Data>False</ExcludeApp_Data>
    <MSDeployServiceURL>waws-prod-bay-003.publish.azurewebsites.windows.net:443</MSDeployServiceURL>
    <DeployIisAppPath>fixitdemo</DeployIisAppPath>
    <RemoteSitePhysicalPath />
    <SkipExtraFilesOnServer>True</SkipExtraFilesOnServer>
    <MSDeployPublishMethod>WMSVC</MSDeployPublishMethod>
    <EnableMSDeployBackup>True</EnableMSDeployBackup>
    <UserName>$fixitdemo</UserName>
    <PublishDatabaseSettings></PublishDatabaseSettings>
  </PropertyGroup>
</Project>
```

As you can see, the script has created a complete test environment, and the whole process is done in about 90

seconds.

If someone else on your team wants to create a test environment, they can just run the script. Not only is it fast, but also they can be confident that they are using an environment identical to the one you're using. You couldn't be quite as confident of that if everyone was setting things up manually by using the management portal UI.

A look at the scripts

There are actually three scripts that do this work. You call one from the command line and it automatically uses the other two to do some of the tasks:

- *New-AzureWebSiteEnv.ps1* is the main script.
  - *New-AzureStorage.ps1* creates the storage account.
  - *New-AzureSql.ps1* creates the databases.

Parameters in the main script

The main script, *New-AzureWebSiteEnv.ps1*, defines several parameters:

```
[CmdletBinding(PositionalBinding=$True)]
Param(
    [Parameter(Mandatory = $true)]
    [ValidatePattern("^[a-z0-9]*$")]
    [String]$Name,
    [String]$Location = "West US",
    [String]$SqlDatabaseUserName = "dbuser",
    [String]$SqlDatabasePassword,
    [String]$StartIPAddress,
    [String]$EndIPAddress
    )
```

Two parameters are required:

- The name of the web app that the script creates. (This is also used for the URL: `<name>.azurewebsites.net`.)
- The password for the new administrative user of the database server that the script creates.

Optional parameters enable you to specify the data center location (defaults to "West US"), database server administrator name (defaults to "dbuser"), and a firewall rule for the database server.

Create the web app

The first thing the script does is create the web app by calling the `New-AzureWebsite` cmdlet, passing in to it the web app name and location parameter values:

```
# Create a new website
$website = New-AzureWebsite -Name $Name -Location $Location -Verbose
```

Create the storage account

Then the main script runs the *New-AzureStorage.ps1* script, specifying "*<websitename>*storage" for the storage account name, and the same data center location as the web app.

```
$storageAccountName = $Name + "storage"

$storage = $scriptPath\New-AzureStorage.ps1" -Name $storageAccountName -Location $Location
```

New-AzureStorage.ps1 calls the `New-AzureStorageAccount` cmdlet to create the storage account, and it returns the account name and access key values. The application will need these values in order to access the blobs and queues in the storage account.

```
# Create a new storage account
New-AzureStorageAccount -StorageAccountName $Name -Location $Location -Verbose

# Get the access key of the storage account
$key = Get-AzureStorageKey -StorageAccountName $Name

# Generate the connection string of the storage account
$connectionString =
"BlobEndpoint=http://$Name.blob.core.windows.net/;QueueEndpoint=http://$Name.queue.core.windows.net/;TableEn
dpoint=http://$Name.table.core.windows.net/;AccountName=$Name;AccountKey=$primaryKey"

#Return a hashtable of storage account values
Return @{AccountName = $Name; AccessKey = $key.Primary; ConnectionString = $connectionString}
```

You might not always want to create a new storage account; you could enhance the script by adding a parameter that optionally directs it to use an existing storage account.

Create the databases

The main script then runs the database creation script, *New-AzureSql.ps1*, after setting up default database and firewall rule names:

```
$sqlAppDatabaseName = "appdb"
$sqlMemberDatabaseName = "memberdb"
$sqlDatabaseServerFirewallRuleName = $Name + "rule"
```

```
# Create a SQL Azure database server, app and member databases
$sql = $scriptPath\New-AzureSql.ps1 `
    -AppDatabaseName $sqlAppDatabaseName `
    -MemberDatabaseName $sqlMemberDatabaseName `
    -UserName $SqlDatabaseUserName `
    -Password $SqlDatabasePassword `
    -FirewallRuleName $sqlDatabaseServerFirewallRuleName `
    -StartIPAddress $StartIPAddress `
    -EndIPAddress $EndIPAddress `
    -Location $Location
```

The database creation script retrieves the dev machine's IP address and sets a firewall rule so the dev machine can connect to and manage the server. The database creation script then goes through several steps to set up the databases:

- Creates the server by using the `New-AzureSqlDatabaseServer` cmdlet.

  ```
  $databaseServer = New-AzureSqlDatabaseServer -AdministratorLogin $UserName -
  AdministratorLoginPassword $Password -Location $Location
  ```

- Creates firewall rules to enable the dev machine to manage the server and to enable the web app to connect to it.

  ```
  # Create a SQL Azure database server firewall rule for the IP address of the machine in which this
  script will run
  # This will also whitelist all the Azure IP so that the website can access the database server
  New-AzureSqlDatabaseServerFirewallRule -ServerName $databaseServerName -RuleName $FirewallRuleName -
  StartIpAddress $StartIPAddress
  -EndIpAddress $EndIPAddress -Verbose
  New-AzureSqlDatabaseServerFirewallRule -ServerName $databaseServer.ServerName -AllowAllAzureServices
  -RuleName "AllowAllAzureIP" -Verbose
  ```

- Creates a database context that includes the server name and credentials, by using the `New-AzureSqlDatabaseServerContext` cmdlet.

  ```
  # Create a database context which includes the server name and credential
  # These are all local operations. No API call to Azure
  $credential = New-PSCredentialFromPlainText -UserName $UserName -Password $Password
  $context = New-AzureSqlDatabaseServerContext -ServerName $databaseServer.ServerName -Credential
  $credential
  ```

  `New-PSCredentialFromPlainText` is a function in the script that calls the `ConvertTo-SecureString` cmdlet to encrypt the password and returns a `PSCredential` object, the same type that the `Get-Credential` cmdlet returns.

- Creates the application database and the membership database by using the `New-AzureSqlDatabase` cmdlet.

  ```
  # Use the database context to create app database
  New-AzureSqlDatabase -DatabaseName $AppDatabaseName -Context $context -Verbose

  # Use the database context to create member database
  New-AzureSqlDatabase -DatabaseName $MemberDatabaseName -Context $context -Verbose
  ```

- Calls a locally defined function to create a connection string for each database. The application will use these connection strings to access the databases.

  ```
  $appDatabaseConnectionString = Get-SQLAzureDatabaseConnectionString -DatabaseServerName
  $databaseServerName -DatabaseName $AppDatabaseName -UserName $UserName -Password $Password
  $memberDatabaseConnectionString = Get-SQLAzureDatabaseConnectionString -DatabaseServerName
  $databaseServerName -DatabaseName $MemberDatabaseName -UserName $UserName -Password $Password
  ```

  Get-SQLAzureDatabaseConnectionString is a function defined in the script that creates the connection string from the parameter values supplied to it.

  ```
  Function Get-SQLAzureDatabaseConnectionString
  {
      Param(
          [String]$DatabaseServerName,
          [String]$DatabaseName,
          [String]$UserName,
          [String]$Password
      )

      Return "Server=tcp:$DatabaseServerName.database.windows.net,1433;Database=$DatabaseName;User
  ID=$UserName@$DatabaseServerName;Password=$Password;Trusted_Connection=False;Encrypt=True;Connection
  Timeout=30;"
  }
  ```

- Returns a hash table with the database server name and the connection strings.

  ```
  Return @{ `
      Server = $databaseServer.ServerName; UserName = $UserName; Password = $Password; `
      AppDatabase = @{Name = $AppDatabaseName; ConnectionString = $appDatabaseConnectionString}; `
      MemberDatabase = @{Name = $MemberDatabaseName; ConnectionString =
  $memberDatabaseConnectionString} `
  }
  ```

The Fix It app uses separate membership and application databases. It's also possible to put both membership

and application data in a single database.

Store app settings and connection strings

Azure has a feature that enables you to store settings and connection strings that automatically override what is returned to the application when it tries to read the `appSettings` or `connectionStrings` collections in the Web.config file. This is an alternative to applying Web.config transformations when you deploy. For more information, see Store sensitive data in Azure later in this e-book.

The environment creation script stores in Azure all of the `appSettings` and `connectionStrings` values that the application needs to access the storage account and databases when it runs in Azure.

```
# Configure app settings for storage account and New Relic
$appSettings = @{ `
    "StorageAccountName" = $storageAccountName; `
    "StorageAccountAccessKey" = $storage.AccessKey; `
    "COR_ENABLE_PROFILING" = "1"; `
    "COR_PROFILER" = "{71DA0A04-7777-4EC6-9643-7D28B46A8A41}"; `
    "COR_PROFILER_PATH" = "C:\Home\site\wwwroot\newrelic\NewRelic.Profiler.dll"; `
    "NEWRELIC_HOME" = "C:\Home\site\wwwroot\newrelic" `
}
```

```
# Configure connection strings for appdb and ASP.NET member db
$connectionStrings = ( `
    @{Name = $sqlAppDatabaseName; Type = "SQLAzure"; ConnectionString = $sql.AppDatabase.ConnectionString},
`
    @{Name = "DefaultConnection"; Type = "SQLAzure"; ConnectionString =
$sql.MemberDatabase.ConnectionString}
)
```

```
# Add the connection string and storage account name/key to the website
Set-AzureWebsite -Name $Name -AppSettings $appSettings -ConnectionStrings $connectionStrings
```

New Relic is a telemetry framework that we demonstrate in the Monitoring and Telemetry chapter. The environment creation script also restarts the web app to make sure that it picks up the New Relic settings.

```
# Restart the website to let New Relic hook kick in
Restart-AzureWebsite -Name $websiteName
```

Preparing for deployment

At the end of the process, the environment creation script calls two functions to create files that will be used by the deployment script.

One of these functions creates a publish profile *(<websitename>.pubxml* file). The code calls the Azure REST API to get the publish settings, and it saves the information in a *.publishsettings* file. Then it uses the information from that file along with a template file (*pubxml.template*) to create the *.pubxml* file that contains the publish profile. This two-step process simulates what you do in Visual Studio: download a *.publishsettings* file and import that to create a publish profile.

The other function uses another template file (website-environment.template) to create a *website-environment.xml* file that contains settings the deployment script will use along with the *.pubxml* file.

Troubleshooting and error handling

Scripts are like programs: they can fail, and when they do you want to know as much as you can about the failure and what caused it. For this reason, the environment creation script changes the value of the `VerbosePreference` variable from `SilentlyContinue` to `Continue` so that all verbose messages are displayed. It also changes the

value of the `ErrorActionPreference` variable from `Continue` to `Stop`, so that the script stops even when it encounters non-terminating errors:

```
# Set the output level to verbose and make the script stop on error
$VerbosePreference = "Continue"
$ErrorActionPreference = "Stop"
```

Before it does any work, the script stores the start time so that it can calculate the elapsed time when it's done:

```
# Mark the start time of the script execution
$startTime = Get-Date
```

After it completes its work, the script displays the elapsed time:

```
# Mark the finish time of the script execution
$finishTime = Get-Date
# Output the time consumed in seconds
Write-Output ("Total time used (seconds): {0}" -f ($finishTime - $startTime).TotalSeconds)
```

And for every key operation the script writes verbose messages, for example:

```
Write-Verbose "[Start] creating $websiteName website in $Location location"
$website = New-AzureWebsite -Name $websiteName -Location $Location -Verbose
Write-Verbose "[Finish] creating $websiteName website in $Location location"
```

Deployment script

What the *New-AzureWebsiteEnv.ps1* script does for environment creation, the *Publish-AzureWebsite.ps1* script does for application deployment.

The deployment script gets the name of the web app from the *website-environment.xml* file created by the environment creation script.

```
[Xml]$envXml = Get-Content "$scriptPath\website-environment.xml"
$websiteName = $envXml.environment.name
```

It gets the deployment user password from the *.publishsettings* file:

```
[Xml]$xml = Get-Content $scriptPath\$websiteName.publishsettings
$password = $xml.publishData.publishProfile.userPWD[0]
$publishXmlFile = Join-Path $scriptPath -ChildPath ($websiteName + ".pubxml")
```

It executes the MSBuild command that builds and deploys the project:

```
& "$env:windir\Microsoft.NET\Framework\v4.0.30319\MSBuild.exe" $ProjectFile `
    /p:VisualStudioVersion=12.0 `
    /p:DeployOnBuild=true `
    /p:PublishProfile=$publishXmlFile `
    /p:Password=$password
```

And if you've specified the `Launch` parameter on the command line, it calls the `Show-AzureWebsite` cmdlet to open your default browser to the website URL.

```
If ($Launch)
{
    Show-AzureWebsite -Name $websiteName
}
```

You can run the deployment script with a command like this one:

```
.\Publish-AzureWebsite.ps1 ..\MyFixIt\MyFixIt.csproj -Launch
```

And when it's done, the browser opens with the site running in the cloud at the `<websitename>.azurewebsites.net` URL.

Summary

With these scripts you can be confident that the same steps will always be executed in the same order using the same options. This helps ensure that each developer on the team doesn't miss something or mess something up or deploy something custom on his own machine that won't actually work the same way in another team member's environment or in production.

In a similar way, you can automate most Azure management functions that you can do in the management portal, by using the REST API, Windows PowerShell scripts, a .NET language API, or a Bash utility that you can run on Linux or Mac.

In the next chapter we'll look at source code and explain why it's important to include your scripts in your source code repository.

Resources

- Install and Configure Windows PowerShell for Azure. Explains how to install the Azure PowerShell cmdlets

and how to install the certificate that you need on your computer in order to manage your Azure account. This is a great place to get started because it also has links to resources for learning PowerShell itself.

- Azure Script Center. WindowsAzure.com portal to resources for developing scripts that manage Azure services, with links to getting started tutorials, cmdlet reference documentation and source code, and sample scripts
- Weekend Scripter: Getting Started with Azure and PowerShell. In a blog dedicated to Windows PowerShell, this post provides a great introduction to using PowerShell for Azure management functions.
- Install and Configure the Azure Cross-Platform Command-Line Interface. Getting-started tutorial for an Azure scripting framework that works on Mac and Linux as well as Windows systems.
- Command-line tools section of the Download Azure SDKs and Tools topic. Portal page for documentation and downloads related to command-line tools for Azure.
- Automating everything with the Azure Management Libraries and .NET. Scott Hanselman introduces the .NET management API for Azure.
- Using Windows PowerShell Scripts to Publish to Dev and Test Environments. MSDN documentation that explains how to use publish scripts that Visual Studio automatically generates for web projects.
- PowerShell Tools for Visual Studio 2013. Visual Studio extension that adds language support for Windows PowerShell in Visual Studio.

Source Control (Building Real-World Cloud Apps with Azure)

2/20/2020 • 13 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

Source control is essential for all cloud development projects, not just team environments. You wouldn't think of editing source code or even a Word document without an undo function and automatic backups, and source control gives you those functions at a project level where they can save even more time when something goes wrong. With cloud source control services, you no longer have to worry about complicated set-up, and you can use Azure Repos source control free for up to 5 users.

The first part of this chapter explains three key best practices to keep in mind:

- Treat automation scripts as source code and version them together with your application code.
- Never check in secrets (sensitive data such as credentials) into a source code repository.
- Set up source branches to enable the DevOps workflow.

The remainder of the chapter gives some sample implementations of these patterns in Visual Studio, Azure, and Azure Repos:

- Add scripts to source control in Visual Studio
- Store sensitive data in Azure
- Use Git in Visual Studio and Azure Repos

Treat automation scripts as source code

When you're working on a cloud project you're changing things frequently and you want to be able to react quickly to issues reported by your customers. Responding quickly involves using automation scripts, as explained in the Automate Everything chapter. All of the scripts that you use to create your environment, deploy to it, scale it, etc., need to be in sync with your application source code.

To keep scripts in sync with code, store them in your source control system. Then if you ever need to roll back changes or make a quick fix to production code which is different from development code, you don't have to waste time trying to track down which settings have changed or which team members have copies of the version you need. You're assured that the scripts you need are in sync with the code base that you need them for, and you're assured that all team members are working with the same scripts. Then whether you need to automate testing and deployment of a hot fix to production or new feature development, you'll have the right script for the code that needs to be updated.

Don't check in secrets

A source code repository is typically accessible to too many people for it to be an appropriately secure place for sensitive data such as passwords. If scripts rely on secrets such as passwords, parameterize those settings so that

they don't get saved in source code, and store your secrets somewhere else.

For example, Azure lets you download files that contain publish settings in order to automate the creation of publish profiles. These files include user names and passwords that are authorized to manage your Azure services. If you use this method to create publish profiles, and if you check in these files to source control, anyone with access to your repository can see those user names and passwords. You can safely store the password in the publish profile itself because it's encrypted and it's in a *.pubxml.user* file that by default is not included in source control.

Structure source branches to facilitate DevOps workflow

How you implement branches in your repository affects your ability to both develop new features and fix issues in production. Here is a pattern that a lot of medium sized teams use:

The master branch always matches code that is in production. Branches underneath master correspond to different stages in the development life cycle. The development branch is where you implement new features. For a small team you might just have master and development, but we often recommend that people have a staging branch between development and master. You can use staging for final integration testing before an update is moved to production.

For big teams there may be separate branches for each new feature; for a smaller team you might have everyone checking in to the development branch.

If you have a branch for each feature, when Feature A is ready you merge its source code changes up into the development branch and down into the other feature branches. This source code merging process can be time-consuming, and to avoid that work while still keeping features separate, some teams implement an alternative called *feature toggles* (also known as *feature flags*). This means all of the code for all of the features is in the same branch, but you enable or disable each feature by using switches in the code. For example, suppose Feature A is a new field for Fix It app tasks, and Feature B adds caching functionality. The code for both features can be in the development branch, but the app will only display the new field when a variable is set to true, and it will only use caching when a different variable is set to true. If Feature A isn't ready to be promoted but the Feature B is ready, you can promote all of the code to Production with the Feature A switch off and the Feature B switch on. You can then finish Feature A and promote it later, all with no source code merging.

Whether or not you use branches or toggles for features, a branching structure like this enables you to flow your code from development into production in an agile and repeatable way.

This structure also enables you to react quickly to customer feedback. If you need to make a quick fix to production, you can also do that efficiently in an agile way. You can create a branch off of master or staging, and when it's ready merge it up into master and down into development and feature branches.

Without a branching structure like this with its separation of production and development branches, a production problem could put you in the position of having to promote new feature code along with your production fix. The new feature code might not be fully tested and ready for production and you might have to do a lot of work backing out changes that aren't ready. Or you might have to delay your fix in order to test changes and get them ready to deploy.

Next you'll see examples of how to implement these three patterns in Visual Studio, Azure, and Azure Repos. These are examples rather than detailed step-by-step how-to-do-it instructions; for detailed instructions that provide all of the context necessary, see the Resources section at the end of the chapter.

Add scripts to source control in Visual Studio

You can add scripts to source control in Visual Studio by including them in a Visual Studio solution folder (assuming your project is in source control). Here's one way to do it.

Create a folder for the scripts in your solution folder (the same folder that has your *.sln* file).

Copy the script files into the folder.

In Visual Studio, add a solution folder to the project.

And add the script files to the solution folder.

The script files are now included in your project and source control is tracking their version changes along with corresponding source code changes.

Store sensitive data in Azure

If you run your application in an Azure Web Site, one way to avoid storing credentials in source control is to store them in Azure instead.

For example, the Fix It application stores in its Web.config file two connection strings that will have passwords in production and a key that gives access to your Azure storage account.

```
<connectionStrings>
  <add name="DefaultConnection" connectionString="Data Source=
(LocalDb)\v11.0;AttachDbFilename=|DataDirectory|\MyFixItMembership.mdf;Initial
Catalog=MyFixItMembership;Integrated Security=True" providerName="System.Data.SqlClient" />
  <add name="appdb" connectionString="Data Source=
(LocalDb)\v11.0;AttachDbFilename=|DataDirectory|\MyFixItTasks.mdf;Initial Catalog=aspnet-
MyFixItTasks;Integrated Security=True" providerName="System.Data.SqlClient" />
</connectionStrings>
<appSettings>
  <add key="webpages:Version" value="3.0.0.0" />
  <add key="webpages:Enabled" value="false" />
  <add key="ClientValidationEnabled" value="true" />
  <add key="UnobtrusiveJavaScriptEnabled" value="true" />
  <add key="StorageAccountName" value="fixitdemostorage" />
  <add key="StorageAccountAccessKey" value="[accesskeyvalue]" />
</appSettings>
```

If you put actual production values for these settings in your *Web.config* file, or if you put them in the *Web.Release.config* file to configure a Web.config transform to insert them during deployment, they'll be stored in the source repository. If you enter the database connection strings into the production publish profile, the password will be in your *.pubxml* file. (You could exclude the *.pubxml* file from source control, but then you lose the benefit of sharing all the other deployment settings.)

Azure gives you an alternative for the **appSettings** and connection strings sections of the *Web.config* file. Here is the relevant part of the **Configuration** tab for a web site in the Azure management portal:

When you deploy a project to this web site and the application runs, whatever values you have stored in Azure override whatever values are in the Web.config file.

You can set these values in Azure by using either the management portal or scripts. The environment creation automation script you saw in the Automate Everything chapter creates an Azure SQL Database, gets the storage and SQL Database connection strings, and stores these secrets in the settings for your web site.

```
# Configure app settings for storage account and New Relic
$appSettings = @{ `
    "StorageAccountName" = $storageAccountName; `
    "StorageAccountAccessKey" = $storage.AccessKey; `
    "COR_ENABLE_PROFILING" = "1"; `
    "COR_PROFILER" = "{71DA0A04-7777-4EC6-9643-7D28B46A8A41}"; `
    "COR_PROFILER_PATH" = "C:\Home\site\wwwroot\newrelic\NewRelic.Profiler.dll"; `
    "NEWRELIC_HOME" = "C:\Home\site\wwwroot\newrelic" `
}
```

```
# Configure connection strings for appdb and ASP.NET member db
$connectionStrings = ( `
    @{Name = $sqlAppDatabaseName; Type = "SQLAzure"; ConnectionString = $sql.AppDatabase.ConnectionString},
`
    @{Name = "DefaultConnection"; Type = "SQLAzure"; ConnectionString =
$sql.MemberDatabase.ConnectionString}
)
```

Notice that the scripts are parameterized so that actual values don't get persisted to the source repository.

When you run locally in your development environment, the app reads your local Web.config file and your connection string points to a LocalDB SQL Server database in the *App_Data* folder of your web project. When you run the app in Azure and the app tries to read these values from the Web.config file, what it gets back and uses are the values stored for the Web Site, not what's actually in Web.config file.

Use Git in Visual Studio and Azure DevOps

You can use any source control environment to implement the DevOps branching structure presented earlier. For distributed teams a distributed version control system (DVCS) might work best; for other teams a centralized system might work better.

Git is a popular distributed version control system. When you use Git for source control, you have a complete copy of the repository with all of its history on your local computer. Many people prefer that because it's easier to continue working when you're not connected to the network -- you can continue to do commits and rollbacks, create and switch branches, and so forth. Even when you're connected to the network, it's easier and quicker to create branches and switch branches when everything is local. You can also do local commits and rollbacks without having an impact on other developers. And you can batch commits before sending them to the server.

Azure Repos offers both Git and Team Foundation Version Control (TFVC; centralized source control). Get started with Azure DevOps here.

Visual Studio 2017 includes built-in, first-class Git support. Here's a quick demo of how that works.

With a project open in Visual Studio, right-click the solution in **Solution Explorer**, and then choose **Add Solution to Source Control**.

Visual Studio asks if you want to use TFVC (centralized version control) or Git.

When you select Git and click **OK**, Visual Studio creates a new local Git repository in your solution folder. The new repository has no files yet; you have to add them to the repository by doing a Git commit. Right-click the solution in **Solution Explorer**, and then click **Commit**.

Visual Studio automatically stages all of the project files for the commit and lists them in **Team Explorer** in the **Included Changes** pane. (If there were some you didn't want to include in the commit, you could select them, right-click, and click **Exclude**.)

Enter a commit comment and click **Commit**, and Visual Studio executes the commit and displays the commit ID.

Now if you change some code so that it's different from what's in the repository, you can easily view the differences. Right-click a file that you've changed, select **Compare with Unmodified**, and you get a comparison display that shows your uncommitted change.

You can easily see what changes you're making and check them in.

Suppose you need to make a branch – you can do that in Visual Studio too. In **Team Explorer**, click **New Branch**.

Enter a branch name, click **Create Branch**, and if you selected **Checkout branch**, Visual Studio automatically checks out the new branch.

You can now make changes to files and check them in to this branch. And you can easily switch between branches and Visual Studio automatically syncs the files to whichever branch you have checked out. In this example the web page title in *_Layout.cshtml* has been changed to "Hot Fix 1" in HotFix1 branch.

If you switch back to the master branch, the contents of the *_Layout.cshtml* file automatically revert to what they are in the master branch.

This a simple example of how you can quickly create a branch and flip back and forth between branches. This feature enables a highly agile workflow using the branch structure and automation scripts presented in the Automate Everything chapter. For example, you can be working in the Development branch, create a hot fix branch off of master, switch to the new branch, make your changes there and commit them, and then switch back to the Development branch and continue what you were doing.

What you've seen here is how you work with a local Git repository in Visual Studio. In a team environment you typically also push changes up to a common repository. The Visual Studio tools also enable you to point to a remote Git repository. You can use GitHub.com for that purpose, or you can use Git and Azure Repos integrated with all the other Azure DevOps capabilities such as work item and bug tracking.

This isn't the only way you can implement an agile branching strategy, of course. You can enable the same agile workflow using a centralized source control repository.

Summary

Measure the success of your source control system based on how quickly you can make a change and get it live in a safe and predictable way. If you find yourself scared to make a change because you have to do a day or two of manual testing on it, you might ask yourself what you have to do process-wise or test-wise so that you can make that change in minutes or at worst no longer than an hour. One strategy for doing that is to implement continuous integration and continuous delivery, which we'll cover in the next chapter.

Resources

For more information about branching strategies, see the following resources:

- Building a Release Pipeline with Team Foundation Server 2012. Microsoft Patterns and Practices documentation. See chapter 6 for a discussion of branching strategies. Advocates feature toggles over feature branches, and if branches for features are used, advocates keeping them short-lived (hours or days at most).
- Version Control Guide. Guide to branching strategies by the ALM Rangers. See Branching Strategies.pdf on the Downloads tab.
- Software Development with Feature Toggles. MSDN Magazine article.
- Feature Toggle. Introduction to feature toggles / feature flags on Martin Fowler's blog.
- Feature Toggles vs Feature Branches. Another blog post about feature toggles, by Dylan Smith.

For more information about how to handle sensitive information that should not be kept in source control repositories, see the following resources:

- Best practices for deploying passwords and other sensitive data to ASP.NET and Azure App Service.

- Azure Web Sites: How Application Strings and Connection Strings Work. Explains the Azure feature that overrides `appSettings` and `connectionStrings` data in the *Web.config* file.
- Custom configuration and application settings in Azure Web Sites - with Stefan Schackow.

For information about other methods for keeping sensitive information out of source control, see ASP.NET MVC: Keep Private Settings Out of Source Control.

Continuous Integration and Continuous Delivery (Building Real-World Cloud Apps with Azure)

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

The first two recommended development process patterns were Automate Everything and Source Control, and the third process pattern combines them. Continuous integration (CI) means that whenever a developer checks in code to the source repository, a build is automatically triggered. Continuous delivery (CD) takes this one step further: after a build and automated unit tests are successful, you automatically deploy the application to an environment where you can do more in-depth testing.

The cloud enables you to minimize the cost of maintaining a test environment because you only pay for the environment resources as long as you're using them. Your CD process can set up the test environment when you need it, and you can take down the environment when you're done testing.

Continuous Integration and Continuous Delivery workflow

Generally we recommend that you do continuous delivery to your development and staging environments. Most teams, even at Microsoft, require a manual review and approval process for production deployment. For a production deployment you might want to make sure it happens when key people on the development team are available for support, or during low-traffic periods. But there's nothing to prevent you from completely automating your development and test environments so that all a developer has to do is check in a change and an environment is set up for acceptance testing.

The following diagram from a Microsoft Patterns and Practices e-book about continuous delivery illustrates a typical workflow. Click the image to see it full size in its original context.

How the cloud enables cost-effective CI and CD

Automating these processes in Azure is easy. Because you're running everything in the cloud, you don't have to buy or manage servers for your builds or your test environments. And you don't have to wait for a server to be available to do your testing on. With every build that you do, you could spin up a test environment in Azure using your automation script, run acceptance tests or more in-depth tests against it, and then when you're done just tear it down. And if you only run that server for 2 hours or 8 hours or a day, the amount of money that you have to pay for it is minimal, because you're only paying for the time that a machine is actually running. For example, the environment required for the Fix it application basically costs about 1 cent per hour if you go one tier up from the free level. Over the course of a month, if you only ran the environment an hour at a time, your testing environment would probably cost less than a latte that you buy at Starbucks.

Azure DevOps Services

Azure DevOps Services provides a number of features to assist you with application development from planning to deployment.

- It supports both Git (distributed) and TFVC (centralized) source control.
- It offers an elastic build service, which means it dynamically creates build servers when they're needed and takes them down when they're done. You can automatically kick off a build when someone checks in source code changes, and you don't have to have allocate and pay for your own build servers that lie idle most of the time. The build service is free as long as you don't exceed a certain number of builds. If you expect to do a high volume of builds, you can pay a little extra for reserved build servers.
- It supports continuous delivery to Azure.
- It supports automated load testing. Load testing is critical to a cloud app but is often neglected until it's too late. Load testing simulates heavy use of an app by thousands of users, enabling you to find bottlenecks and improve throughput —before you release the app to production.
- It supports team room collaboration, which facilitates real-time communication and collaboration for small agile teams.
- It supports agile project management.

For more information on the continuous integration and delivery features of Azure DevOps Services, see the Azure DevOps documentation.

If you're looking for a turn-key project management, team collaboration, and source control solution, check out Azure DevOps Services. Sign up at Azure DevOps Services.

Summary

The first three cloud development patterns have been about how to implement a repeatable, reliable, predictable development process with low cycle time. In the next chapter we start to look at architectural and coding patterns.

Resources

For more information, see Deploy a web app in Azure App Service.

See also the following resources:

- Building a Release Pipeline with Team Foundation Server 2012. E-book, hands-on labs, and sample code by Microsoft Patterns and Practices, provides an in-depth introduction to continuous delivery. Covers use of Visual Studio Lab Management and Visual Studio Release Management.
- ALM Rangers DevOps Tooling and Guidance. The ALM Rangers introduced the DevOps Workbench sample companion solution and practical guidance in collaboration with the Patterns & Practices book *Building a Release Pipeline with TFS 2012*, as a great way to start learning the concepts of DevOps & Release Management for TFS 2012 and to kick the tires. The guidance shows how to build once and deploy to multiple environments.
- Testing for Continuous Delivery with Visual Studio 2012. E-book by Microsoft Patterns and Practices, explains how to integrate automated testing with continuous delivery.
- WindowsAzureDeploymentTracker. Source code for a tool designed to capture a build from TFS (based on a label), build it, package it, allow someone in the DevOps role to configure specific aspects of it, and push it into Azure. The tool tracks the deployment process in order to enable operations to "roll back" to a previously deployed version. The tool has no external dependencies and can function stand-alone using TFS APIs and the Azure SDK.

Web Development Best Practices (Building Real-World Cloud Apps with Azure)

2/20/2020 • 10 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

The first three patterns were about setting up an agile development process; the rest are about architecture and code. This one is a collection of web development best practices:

- Stateless web servers behind a smart load balancer.
- Avoid session state (or if you can't avoid it, use distributed cache rather than a database).
- Use a CDN to edge-cache static file assets (images, scripts).
- Use .NET 4.5's async support to avoid blocking calls.

These practices are valid for all web development, not just for cloud apps, but they're especially important for cloud apps. They work together to help you make optimal use of the highly flexible scaling offered by the cloud environment. If you don't follow these practices, you'll run into limitations when you try to scale your application.

Stateless web tier behind a smart load balancer

Stateless web tier means you don't store any application data in the web server memory or file system. Keeping your web tier stateless enables you to both provide a better customer experience and save money:

- If the web tier is stateless and it sits behind a load balancer, you can quickly respond to changes in application traffic by dynamically adding or removing servers. In the cloud environment where you only pay for server resources for as long as you actually use them, that ability to respond to changes in demand can translate into huge savings.
- A stateless web tier is architecturally much simpler to scale out the application. That too enables you to respond to scaling needs more quickly, and spend less money on development and testing in the process.
- Cloud servers, like on-premises servers, need to be patched and rebooted occasionally; and if the web tier is stateless, re-routing traffic when a server goes down temporarily won't cause errors or unexpected behavior.

Most real-world applications do need to store state for a web session; the main point here is not to store it on the web server. You can store state in other ways, such as on the client in cookies or out of process server-side in ASP.NET session state using a cache provider. You can store files in Windows Azure Blob storage instead of the local file system.

As an example of how easy it is to scale an application in Windows Azure Web Sites if your web tier is stateless, see the **Scale** tab for a Windows Azure Web Site in the management portal:

If you want to add web servers, you can just drag the instance count slider to the right. Set it to 5 and click **Save**, and within seconds you have 5 web servers in Windows Azure handling your web site's traffic.

You can just as easily set the instance count down to 3 or back down to 1. When you scale back, you start saving money immediately because Windows Azure charges by the minute, not by the hour.

You can also tell Windows Azure to automatically increase or decrease the number of web servers based on CPU usage. In the following example, when CPU usage goes below 60%, the number of web servers will decrease to a

minimum of 2, and if CPU usage goes above 80%, the number of web servers will be increased up to a maximum of 4.

Or what if you know that your site will only be busy during working hours? You can tell Windows Azure to run multiple servers during the daytime and decrease to a single server evenings, nights, and weekends. The following series of screen shots shows how to set up the web site to run one server in off hours and 4 servers during work hours from 8 AM to 5 PM.

And of course all of this can be done in scripts as well as in the portal.

The ability of your application to scale out is almost unlimited in Windows Azure, so long as you avoid impediments to dynamically adding or removing server VMs, by keeping the web tier stateless.

Avoid session state

It's often not practical in a real-world cloud app to avoid storing some form of state for a user session, but some approaches impact performance and scalability more than others. If you have to store state, the best solution is to keep the amount of state small and store it in cookies. If that isn't feasible, the next best solution is to use ASP.NET session state with a provider for distributed, in-memory cache. The worst solution from a performance and scalability standpoint is to use a database backed session state provider.

Use a CDN to cache static file assets

CDN is an acronym for Content Delivery Network. You provide static file assets such as images and script files to a CDN provider, and the provider caches these files in data centers all over the world so that wherever people access your application, they get relatively quick response and low latency for the cached assets. This speeds up the overall load time of the site and reduces the load on your web servers. CDNs are especially important if you are reaching an audience that is widely distributed geographically.

Windows Azure has a CDN, and you can use other CDNs in an application that runs in Windows Azure or any web hosting environment.

Use .NET 4.5's async support to avoid blocking calls

.NET 4.5 enhanced the C# and VB programming languages in order to make it much simpler to handle tasks asynchronously. The benefit of asynchronous programming is not just for parallel processing situations such as when you want to kick off multiple web service calls simultaneously. It also enables your web server to perform more efficiently and reliable under high load conditions. A web server only has a limited number of threads available, and under high load conditions when all of the threads are in use, incoming requests have to wait until threads are freed up. If your application code doesn't handle tasks like database queries and web service calls asynchronously, many threads are unnecessarily tied up while the server is waiting for an I/O response. This limits the amount of traffic the server can handle under high load conditions. With asynchronous programming, threads that are waiting for a web service or database to return data are freed up to service new requests until the data the is received. In a busy web server, hundreds or thousands of requests can then be processed promptly which would otherwise be waiting for threads to be freed up.

As you saw earlier, it's as easy to decrease the number of web servers handling your web site as it is to increase them. So if a server can achieve greater throughput, you don't need as many of them and you can decrease your costs because you need fewer servers for a given traffic volume than you otherwise would.

Support for the .NET 4.5 asynchronous programming model is included in ASP.NET 4.5 for Web Forms, MVC, and Web API; in Entity Framework 6, and in the Windows Azure Storage API.

Async support in ASP.NET 4.5

In ASP.NET 4.5, support for asynchronous programming has been added not just to the language but also to the MVC, Web Forms, and Web API frameworks. For example, an ASP.NET MVC controller action method receives data from a web request and passes the data to a view which then creates the HTML to be sent to the browser. Frequently the action method needs to get data from a database or web service in order to display it in a web page or to save data entered in a web page. In those scenarios it's easy to make the action method asynchronous: instead of returning an *ActionResult* object, you return *Task<ActionResult>* and mark the method with the *async* keyword. Inside the method, when a line of code kicks off an operation that involves wait time, you mark it with the await keyword.

Here is a simple action method that calls a repository method for a database query:

```
public ActionResult Index()
{
    string currentUser = User.Identity.Name;
    var result = fixItRepository.FindOpenTasksByOwner(currentUser);

    return View(result);
}
```

And here is the same method that handles the database call asynchronously:

```
public async Task<ActionResult> Index()
{
    string currentUser = User.Identity.Name;
    var result = await fixItRepository.FindOpenTasksByOwnerAsync(currentUser);

    return View(result);
}
```

Under the covers the compiler generates the appropriate asynchronous code. When the application makes the call to `FindTaskByIdAsync`, ASP.NET makes the `FindTask` request and then unwinds the worker thread and makes it available to process another request. When the `FindTask` request is done, a thread is restarted to continue processing the code that comes after that call. During the interim between when the `FindTask` request is initiated and when the data is returned, you have a thread available to do useful work which otherwise would be tied up waiting for the response.

There is some overhead for asynchronous code, but under low-load conditions, that overhead is negligible, while under high-load conditions you're able to process requests that otherwise would be held up waiting for available threads.

It has been possible to do this kind of asynchronous programming since ASP.NET 1.1, but it was difficult to write, error-prone, and difficult to debug. Now that we've simplified the coding for it in ASP.NET 4.5, there's no reason not to do it anymore.

Async support in Entity Framework 6

As part of async support in 4.5 we shipped async support for web service calls, sockets, and file system I/O, but the most common pattern for web applications is to hit a database, and our data libraries didn't support async. Now Entity Framework 6 adds async support for database access.

In Entity Framework 6 all methods that cause a query or command to be sent to the database have async versions. The example here shows the async version of the *Find* method.

```
public async Task<FixItTask> FindTaskByIdAsync(int id)
{
    FixItTask fixItTask = null;
    Stopwatch timespan = Stopwatch.StartNew();

    try
    {
        fixItTask = await db.FixItTasks.FindAsync(id);

        timespan.Stop();
        log.TraceApi("SQL Database", "FixItTaskRepository.FindTaskByIdAsync", timespan.Elapsed, "id={0}",
id);
    }
    catch(Exception e)
    {
        log.Error(e, "Error in FixItTaskRepository.FindTaskByIdAsynx(id={0})", id);
    }

    return fixItTask;
}
```

And this async support works not just for inserts, deletes, updates, and simple finds, it also works with LINQ queries:

```
public async Task<List<FixItTask>> FindOpenTasksByOwnerAsync(string userName)
{
    Stopwatch timespan = Stopwatch.StartNew();

    try
    {
        var result = await db.FixItTasks
            .Where(t => t.Owner == userName)
            .Where(t=>t.IsDone == false)
            .OrderByDescending(t => t.FixItTaskId).ToListAsync();

        timespan.Stop();
        log.TraceApi("SQL Database", "FixItTaskRepository.FindTasksByOwnerAsync", timespan.Elapsed,
"username={0}", userName);

        return result;
    }
    catch (Exception e)
    {
        log.Error(e, "Error in FixItTaskRepository.FindTasksByOwnerAsync(userName={0})", userName);
        return null;
    }
}
```

There's an `Async` version of the `ToList` method because in this code that's the method that causes a query to be sent to the database. The `Where` and `OrderByDescending` methods only configure the query, while the `ToListAsync` method executes the query and stores the response in the `result` variable.

Summary

You can implement the web development best practices outlined here in any web programming framework and any cloud environment, but we have tools in ASP.NET and Windows Azure to make it easy. If you follow these patterns, you can easily scale out your web tier, and you'll minimize your expenses because each server will be able to handle more traffic.

The next chapter looks at how the cloud enables single sign-on scenarios.

Single Sign-On (Building Real-World Cloud Apps with Azure)

2/20/2020 • 8 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

There are many security issues to think about when you're developing a cloud app, but for this series we'll focus on just one: single sign-on. A question people often ask is this: "I'm primarily building apps for the employees of my company; how do I host these apps in the cloud and still enable them to use the same security model that my employees know and use in the on-premises environment when they're running apps that are hosted inside the firewall?" One of the ways we enable this scenario is called Azure Active Directory (Azure AD). Azure AD enables you to make enterprise line-of-business (LOB) apps available over the Internet, and it enables you to make these apps available to business partners as well.

Introduction to Azure AD

Azure AD provides Active Directory in the cloud. Key features include the following:

- It integrates with on-premises Active Directory.
- It enables single sign-on with your apps.
- It supports open standards such as SAML, WS-Fed, and OAuth 2.0.
- It supports Enterprise Graph REST API.

Suppose you have an on-premises Windows Server Active Directory environment that you use to enable employees to sign on to Intranet apps:

What Azure AD enables you to do is create a directory in the cloud. It's a free feature and easy to set up.

It can be entirely independent from your on-premises Active Directory; you can put anyone you want in it and authenticate them in Internet apps.

Or you can integrate it with your on-premises AD.

Now all the employees who can authenticate on-premises can also authenticate over the Internet – without you having to open up a firewall or deploy any new servers in your data center. You can continue to leverage all the existing Active Directory environment that you know and use today to give your internal apps single-sign on capability.

Once you've made this connection between AD and Azure AD, you can also enable your web apps and your mobile devices to authenticate your employees in the cloud, and you can enable third-party apps, such as Office 365, SalesForce.com, or Google apps, to accept your employees' credentials. If you're using Office 365, you're already set up with Azure AD because Office 365 uses Azure AD for authentication and authorization.

The beauty of this approach is that any time your organization adds or deletes a user, or a user changes a password, you use the same process that you use today in your on-premises environment. All of your on-premises AD changes are automatically propagated to the cloud environment.

If your company is using or moving to Office 365, the good news is that you'll have Azure AD set up automatically because Office 365 uses Azure AD for authentication. So you can easily use in your own apps the same authentication that Office 365 uses.

Set up an Azure AD tenant

an Azure AD directory is called an Azure AD tenant, and setting up a tenant is pretty easy. We'll show you how it's done in the Azure Management Portal in order to illustrate the concepts, but of course like the other portal functions you can also do it by using a script or management API.

In the management portal click the Active Directory tab.

You automatically have one Azure AD tenant for your Azure account, and you can click the **Add** button at the

bottom of the page to create additional directories. You might want one for a test environment and one for production, for example. Think carefully about what you name a new directory. If you use your name for the directory and then you use your name again for one of the users, that can be confusing.

The portal has full support for creating, deleting, and managing users within this environment. For example, to add a user go to the **Users** tab and click the **Add User** button.

You can create a new user who exists only in this directory, or you can register a Microsoft Account as a user in this directory, or register or a user from another Azure AD directory as a user in this directory. (In a real directory, the default domain would be ContosoTest.onmicrosoft.com. You can also use a domain of your own choosing, like contoso.com.)

You can assign the user to a role.

And the account is created with a temporary password.

The users you create this way can immediately log in to your web apps using this cloud directory.

What's great for enterprise single sign-on, though, is the **Directory Integration** tab:

If you enable directory integration, and download a tool, you can sync this cloud directory with your existing on-premises Active Directory that you're already using inside your organization. Then all of the users stored in your directory will show up in this cloud directory. Your cloud apps can now authenticate all of your employees using their existing Active Directory credentials. And all this is free – both the sync tool and Azure AD itself.

The tool is a wizard that is easy to use, as you can see from these screen shots. These are not complete instructions, just an example showing you the basic process. For more detailed how-to-do-it information, see the links in the Resources section at the end of the chapter.

Click **Next**, and then enter your Azure Active Directory credentials.

Click **Next**, and then enter your on-premises AD credentials.

Click **Next**, and then indicate if you want to store a hash of your AD passwords in the cloud.

The password hash that you can store in the cloud is a one-way hash; actual passwords are never stored in Azure AD. If you decide against storing hashes in the cloud, you'll have to use Active Directory Federation Services (ADFS). There are also other factors to consider when choosing whether or not to use ADFS. The ADFS option requires a few additional configuration steps.

If you choose to store hashes in the cloud, you're done, and the tool starts synchronizing directories when you click **Next**.

And in a few minutes you're done.

You only have to run this on one domain controller in the organization, on Windows 2003 or higher. And no need to reboot. When you're done, all of your users are in the cloud and you can do single sign-on from any web or mobile application, using SAML, OAuth, or WS-Fed.

Sometimes we get asked about how secure this is – does Microsoft use it for their own sensitive business data? And the answer is yes we do. For example, if you go to the internal Microsoft SharePoint site at https://microsoft.sharepoint.com/, you get prompted to log in.

Microsoft has enabled ADFS, so when you enter a Microsoft ID, you get redirected to an ADFS log-in page.

And once you enter credentials stored in an internal Microsoft AD account, you have access to this internal application.

We're using an AD sign-in server mainly because we already had ADFS set up before Azure AD became available, but the log-in process is going through an Azure AD directory in the cloud. We put our important documents, source control, performance management files, sales reports, and more, in the cloud and are using this exact same solution to secure them.

Create an ASP.NET app that uses Azure AD for single sign-on

Visual Studio makes it really easy to create an app that uses Azure AD for single sign-on, as you can see from a few screen shots.

When you create a new ASP.NET application, either MVC or Web Forms, the default authentication method is ASP.NET Identity. To change that to Azure AD, you click a **Change Authentication** button.

Select Organizational Accounts, enter your domain name, and then select Single Sign On.

You can also give the app read or read/write permission for directory data. If you do that, it can use the Azure Graph REST API to look up users' phone number, find out if they're in the office, when they last logged on, etc.

That's all you have to do - Visual Studio asks for the credentials for an administrator for your Azure AD tenant, and then it configures both your project and your Azure AD tenant for the new application.

When you run the project, you'll see a sign-in page, and you can sign in with credentials of a user in your Azure AD directory.

Feedback

When you deploy the app to Azure, all you have to do is select an **Enable Organizational Authentication** check box, and once again Visual Studio takes care of all the configuration for you.

These screen shots come from a complete step-by-step tutorial that shows how to build an app that uses Azure AD authentication: Developing ASP.NET Apps with Azure Active Directory.

Summary

In this chapter you saw that Azure Active Directory, Visual Studio, and ASP.NET, make it easy to set up single sign-on in Internet applications for your organization's users. Your users can sign on in Internet apps using the same credentials they use to sign on using Active Directory in your internal network.

The next chapter looks at the data storage options available for a cloud app.

Data Storage Options (Building Real-World Cloud Apps with Azure)

2/20/2020 • 26 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

Most people are used to relational databases, and they tend to overlook other data storage options when they're designing a cloud app. The result can be suboptimal performance, high expenses, or worse, because NoSQL (non-relational) databases can handle some tasks more efficiently than relational databases. When customers ask us for help resolving a critical data storage problem, it's often because they have a relational database where one of the NoSQL options would have worked better. In those situations the customer would have been better off if they had implemented the NoSQL solution before deploying the app to production.

On the other hand, it would also be a mistake to assume that a NoSQL database can do everything well or well enough. There is no single best data management choice for all data storage tasks; different data management solutions are optimized for different tasks. Most real-world cloud apps have a variety of data storage requirements and are often served best by a combination of multiple data storage solutions.

The purpose of this chapter is to give you a broader sense of the data storage options available to a cloud app, and some basic guidance on how to choose the ones that fit your scenario. It's best to be aware of the options available to you and think about their strengths and weaknesses before you develop an application. Changing data storage options in a production app can be extremely difficult, like having to change a jet engine while the plane is in flight.

Data storage options on Azure

The cloud makes it relatively easy to use a variety of relational and NoSQL data stores. Here are some of the data storage platforms that you can use in Azure.

Relational	Key/Value	Column Family	Document	Graph
• Windows Azure SQL Database • SQL Server • Oracle • MySQL • SQL Compact • SQLite • Postgres	• Windows Azure Blob Storage • Windows Azure Table Storage • Windows Azure Cache • Redis • Memcached • Riak	• Cassandra • HBase	• MongoDB • RavenDB • CouchDB	• Neo4J

The table shows four types of NoSQL databases:

- Key/value databases store a single serialized object for each key value. They're good for storing large volumes of data where you want to get one item for a given key value and you don't have to query based on other properties of the item.

  Azure Blob storage is a key/value database that functions like file storage in the cloud, with key values that correspond to folder and file names. You retrieve a file by its folder and file name, not by searching for values in the file contents.

  Azure Table storage is also a key/value database. Each value is called an *entity* (similar to a row, identified by a partition key and row key) and contains multiple *properties* (similar to columns, but not all entities in a table have to share the same columns). Querying on columns other than the key is extremely inefficient and should be avoided. For example, you can store user profile data, with one partition storing information about a single user. You could store data such as user name, password hash, birth date, and so forth, in separate properties of one entity or in separate entities in the same partition. But you wouldn't want to query for all users with a given range of birth dates, and you can't execute a join query between your profile table and another table. Table storage is more scalable and less expensive than a relational database, but it doesn't enable complex queries or joins.

- Documentdatabases are key/value databases in which the values are *documents*. "Document" here isn't used in the sense of a Word or Excel document but means a collection of named fields and values, any of which could be a child document. For example, in an order history table an order document might have order number, order date, and customer fields; and the customer field might have name and address fields. The database encodes field data in a format such as XML, YAML, JSON, or BSON; or it can use plain text. One feature that sets document databases apart from key/value databases is the ability to query on non-key fields and define secondary indexes to make querying more efficient. This ability makes a document database more suitable for applications that need to retrieve data based on criteria more complex than the value of the document key. For example, in a sales order history document database you could query on various fields such as product ID, customer ID, customer name, and so forth. MongoDB is a popular document database.

- Column-family databases are key/value data stores that enable you to structure data storage into collections of related columns called column families. For example, a census database might have one group of columns for a person's name (first, middle, last), one group for the person's address, and one group for the person's profile information (DOB, gender, etc.). The database can then store each column family in a separate partition while keeping all of the data for one person related to the same key. You can then read all profile information without having to read through all of the name and address information

as well. Cassandra is a popular column-family database.

- Graph databases store information as a collection of objects and relationships. The purpose of a graph database is to enable an application to efficiently perform queries that traverse the network of objects and the relationships between them. For example, the objects might be employees in a human resources database, and you might want to facilitate queries such as "find all employees who directly or indirectly work for Scott." Neo4j is a popular graph database.

Compared to relational databases, the NoSQL options offer far greater scalability and cost-effectiveness for storage and analysis of unstructured data. The tradeoff is that they don't provide the rich queryability and robust data integrity capabilities of relational databases. NoSQL would work well for IIS log data, which involves high volume with no need for join queries. NoSQL would not work so well for banking transactions, which requires absolute data integrity and involves many relationships to other account-related data.

There is also a newer category of database platform called NewSQL that combines the scalability of a NoSQL database with the queryability and transactional integrity of a relational database. NewSQL databases are designed for distributed storage and query processing, which is often hard to implement in "OldSQL" databases. NuoDB is an example of a NewSQL database that can be used on Azure.

Hadoop and MapReduce

The high volumes of data that you can store in NoSQL databases may be difficult to analyze efficiently in a timely manner. To do that you can use a framework like Hadoop which implements MapReduce functionality. Essentially what a MapReduce process does is the following:

- Limit the size of the data that needs to be processed by selecting out of the data store only the data you actually need to analyze. For example, you want to know the makeup of your user base by birth year, so you select only birth years out of your user profile data store.
- Break down the data into parts and send them to different computers for processing. Computer A calculates the number of people with 1950-1959 dates, computer B does 1960-1969, etc. This group of computers is called a *Hadoop cluster*.
- Put the results of each part back together after the processing on the parts is done. You now have a relatively short list of how many people for each birth year and the task of calculating percentages in this overall list is manageable.

On Azure, HDInsight enables you to process, analyze, and gain new insights from big data using the power of Hadoop. For example, you could use it to analyze web server logs:

- Enable web server logging to your storage account. This sets up Azure to write logs to the Blob Service for every HTTP request to your application. The Blob Service is basically cloud file storage, and it integrates nicely with HDInsight.

- As the app gets traffic, web server IIS logs are written to Blob storage.

- In the portal, click **New** - **Data Services** - **HDInsight** - **Quick Create**, and specify an HDInsight cluster name, cluster size (number of HDInsight cluster data nodes), and a user name and password for the HDInsight cluster.

You can now set up MapReduce jobs to analyze your logs and get answers to questions such as:

- What times of day does my app get the most or least traffic?
- What countries is my traffic coming from?
- What is the average neighborhood income of the areas my traffic comes from. (There's a public dataset that gives you neighborhood income by IP address, and you can match that against IP address in the web server logs.)
- How does neighborhood income correlate to specific pages or products in the site?

You could then use the answers to questions like these to target ads based on the likelihood a customer would be interested in or likely to buy a particular product.

As explained in the Automate Everything chapter, most functions that you can do in the portal can be automated, and that includes setting up and executing HDInsight analysis jobs. A typical HDInsight script might contain the following steps:

- Provision an HDInsight cluster and link it to your storage account for Blob storage input.
- Upload the MapReduce job executables (.jar or .exe files) to the HDInsight cluster.
- Submit a MapReduce that stores the output data to Blob storage.
- Wait for the job to complete.
- Delete the HDInsight cluster.
- Access the output from Blob storage.

By running a script that does all this, you minimize the amount of time that the HDInsight cluster is provisioned, which minimizes your costs.

Platform as a Service (PaaS) versus Infrastructure as a Service (IaaS)

The data storage options listed earlier include both Platform-as-a-Service (PaaS) and Infrastructure-as-a-Service (IaaS) solutions. PaaS means that we manage the hardware and software infrastructure and you just use the service. SQL Database is a PaaS feature of Azure. You ask for databases, and behind the scenes Azure sets up and configures the VMs and sets up the databases on them. You don't have direct access to the VMs and don't have to manage them.IaaS means that you set up, configure, and manage VMs that run in our data center infrastructure, and you put whatever you want on them. We provide a gallery of pre-configured VM images for common VM

configurations. For example, you can install pre-configured VM images for Windows Server 2008, Windows Server 2012, BizTalk Server, Oracle WebLogic Server, Oracle Database, etc.

PaaS data solutions that Azure offers include:

- Azure SQL Database (formerly known as SQL Azure). A cloud relational database based on SQL Server.
- Azure Table storage. A key/value NoSQL database.
- Azure Blob storage. File storage in the cloud.

For IaaS, you can run anything you can load onto a VM, for example:

- Relational databases such as SQL Server, Oracle, MySQL, SQL Compact, SQLite, or Postgres.
- Key/value data stores such as Memcached, Redis, Cassandra, and Riak.
- Column data stores such as HBase.
- Document databases such as MongoDB, RavenDB, and CouchDB.
- Graph databases such as Neo4j.

The IaaS option gives you almost unlimited data storage options, and many of them are especially easy to use because you can create VMs using preconfigured images. For example, in the management portal go to **Virtual Machines**, click the **Images** tab, and click **Browse VM Depot**.

You then see a list of hundreds of preconfigured VM images, and you can create a VM from an image that has a database management system preinstalled, such as MongoDB, Neo4J, Redis, Cassandra, or CouchDB:

Azure makes IaaS data storage options as easy to use as possible, but the PaaS offerings have many advantages that make them more cost-effective and practical for many scenarios:

- You don't have to create VMs, you just use the portal or a script to set up a data store. If you want a 200 terabyte data store, you can just click a button or run a command, and in seconds it's ready for you to use.
- You don't have to manage or patch the VMs used by the service; Microsoft does that for you automatically.- You don't have to worry about setting up infrastructure for scaling or high availability; Microsoft handles all that for you.
- You don't have to buy licenses; license fees are included in the service fees.
- You only pay for what you use.

PaaS data storage options in Azure include offerings by third-party providers. For example, you can choose the MongoLab Add-On from the Azure Store to provision a MongoDB database as a service.

Choosing a data storage option

No one approach is right for all scenarios. If anyone says that this technology is the answer, the first thing to ask is "What is the question?", because different solutions are optimized for different things. There are definite advantages to the relational model; that's why it's been around for so long. But there are also down-sides to SQL that can be addressed with a NoSQL solution.

Often what we see work best is a compositional approach, where you use SQL and NoSQL in a single solution. Even when people say they're embracing NoSQL, if you drill into what they're doing you often find that they're using several different NoSQL frameworks: they're using CouchDB, and Redis, and Riak for different things. Even Facebook, which uses NoSQL extensively, uses different NoSQL frameworks for different parts of the service. The flexibility to mix and match data storage approaches is one of the things that's nice about the cloud, because it's easy to use multiple data solutions and integrate them in a single app.

Here are some questions to think about when you're choosing an approach:

DATA SEMANTIC	- WHAT IS THE CORE DATA STORAGE AND DATA ACCESS SEMANTIC (ARE YOU STORING RELATIONAL OR UNSTRUCTURED DATA)? UNSTRUCTURED DATA SUCH AS MEDIA FILES FITS BEST IN BLOB STORAGE; A COLLECTION OF RELATED DATA SUCH AS PRODUCTS, INVENTORIES, SUPPLIERS, CUSTOMER ORDERS, ETC., FITS BEST IN A RELATIONAL DATABASE.
Query support	- How easy is it to query the data? - What types of questions can be efficiently asked? Key/value data stores are very good at getting a single row given a key value but not so good for complex queries. For a user profile data store where you are always getting the data for one particular user, a key/value data store could work well; for a product catalog where you want to get different groupings based on various product attributes a relational database might work better. NoSQL databases can store large volumes of data efficiently, but you have to structure the database around how the app queries the data, and this makes ad hoc queries harder to do. With a relational database, you can build almost any kind of query.
Functional projection	- Can questions, aggregations, etc., be executed server-side? If I run SELECT COUNT(*) from a table in SQL, it will very efficiently do all the work on the server and return the number I'm looking for. If I want the same calculation from a NoSQL data store that doesn't support aggregation, this is an inefficient "unbounded query" and will probably time out. Even if the query succeeds I have to retrieve all of the data from the server to the client and count the rows on the client. - What languages or types of expressions can be used? With a relational database I can use SQL. With some NoSQL databases such as Azure Table storage, I'll be using OData, and all I can do is filter on primary key and get projections (select a subset of the available fields).
Ease of scalability	- How often and how much will the data need to scale? - Does the platform natively implement scale-out? - How easy is it to add/remove capacity (size and throughput)? Relational databases and tables aren't automatically partitioned to make them scalable, so they are difficult to scale beyond certain limitations. NoSQL data stores like Azure Table storage inherently partition everything, and there is almost no limit to adding partitions. You can readily scale Table Storage up to 200 terabytes, but the maximum database size for Azure SQL Database is 500 gigabytes. You can scale relational data by partitioning it into multiple databases, but setting up an application to support that model involves a lot of programming work.
Instrumentation and Manageability	- How easy is the platform to instrument, monitor, and manage? You will need to keep informed about the health and performance of your data store, so you need to know up front what metrics a platform gives you for free, and what you have to develop yourself.
Operations	- How easy is the platform to deploy and run on Azure? PaaS? IaaS? Linux? Table Storage and SQL Database are easy to set up on Azure. Platforms that aren't built-in Azure PaaS solutions require more effort.

DATA SEMANTIC	- WHAT IS THE CORE DATA STORAGE AND DATA ACCESS SEMANTIC (ARE YOU STORING RELATIONAL OR UNSTRUCTURED DATA)? UNSTRUCTURED DATA SUCH AS MEDIA FILES FITS BEST IN BLOB STORAGE; A COLLECTION OF RELATED DATA SUCH AS PRODUCTS, INVENTORIES, SUPPLIERS, CUSTOMER ORDERS, ETC., FITS BEST IN A RELATIONAL DATABASE.
API Support	- Is an API available that makes it easy to work with the platform? For the Azure Table Service there's an SDK with a .NET API that supports the .NET 4.5 asynchronous programming model. If you're writing a .NET app, it'll be much easier to write and test code for the Azure Table Service compared to another key/value column data store platform that has no API or a less comprehensive one.
Transactional integrity and data consistency	- Is it critical that the platform support transactions in order to guarantee data consistency? For keeping track of bulk emails sent, performance and low data storage cost might be more important than automatic support for transactions or referential integrity in the data platform, making the Azure Table Service a good choice. For tracking bank account balances or purchase orders a relational database platform that provides strong transactional guarantees would be a better choice.
Business continuity	- How easy are backup, restore, and disaster recovery? Sooner or later production data will get corrupted and you'll need an undo function. Relational databases often have more fine-grained restore capabilities, such as the ability to restore to a point in time. Understanding what restore features are available in each platform you're considering is an important factor to consider.
Cost	- If more than one platform can support your data workload, how do they compare in cost? For example, if you use ASP.NET Identity, you can store user profile data in Azure Table Service or Azure SQL Database. If you don't need the rich querying facilities of SQL Database, you might choose Azure Tables in part because it costs much less for a given amount of storage.

What we generally recommend is know the answer to the questions in each of these categories before you choose your data storage solutions.

In addition, your workload might have specific requirements that some platforms can support better than others. For example:

- Does your application require audit capabilities?
- What are your data longevity requirements -- do you require automated archival or purging capabilities?
- Do you have specialized security needs? For example, the data includes PII (personally identifiable information) but you have to be able to make sure that PII is excluded from query results.
- If you have some data that can't be stored in the cloud for regulatory or technological reasons, you might need a cloud data storage platform that facilitates integrating with your on-premises storage.

Demo – using SQL Database in Azure

The Fix It app uses a relational database to store tasks. The environment creation Windows PowerShell script shown in the Automate Everything chapter creates two SQL Database instances. You can see these in the portal by clicking the **SQL Databases** tab.

It's also easy to create databases by using the portal.

Click **New -- Data Services -- SQL Database -- Quick Create**, enter a database name, choose a server you already have in your account or create a new one, and click **Create SQL Database**.

Wait several seconds, and you have a database in Azure ready for you to use.

So Azure does in a few seconds what it may take you a day or a week or longer to accomplish in the on-premises environment. And since you can just as easily create databases automatically in a script or by using a management API, you can dynamically scale out by spreading your data across multiple databases, so long as your application has been programmed for that.

This is an example of our Platform-as-a-Service model. You don't have to manage the servers, we do it. You don't have to worry about backups, we do it. It's running in high availability – the data in the database is replicated across three servers automatically. If a machine dies, we automatically fail over and you lose no data. The server is patched regularly, you don't need to worry about that.

Click a button and you get the exact connection string you need and can immediately start using the new database.

The Dashboard shows you connection history and amount of storage used.

You can manage databases in the portal or by using SQL Server tools you're already familiar with, including SQL Server Management Studio (SSMS) and the Visual Studio tools SQL Server Object Explorer (SSOX) and Server Explorer.

Another nice thing is the pricing model. You can start development with a free 20 MB database, and a production database starts at about $5 per month. You pay only for the amount of data you actually store in the database, not the maximum capacity. You don't have to buy a license.

SQL Database is easy to scale. For the Fix It app, the database we create in our automation script is capped at 1 gig. If you want to scale it up to 150 gig, you can just go into the portal and change that setting, or execute a REST API command, and in seconds you have a 150 gig database that you can deploy data into.

That's the power of the cloud to stand up infrastructure quickly and easily and start using it immediately.

The Fix It app uses two SQL databases, one for membership (authentication and authorization) and one for data, and this is all you have to do to provision it and scale it. You saw earlier how to provision the databases through Windows PowerShell scripts, and now you've also seen how easy it is to do in the portal.

Entity Framework versus direct database access using ADO.NET

The Fix It app accesses these databases by using the Entity Framework, Microsoft's recommended ORM (object-relational mapper) for .NET applications. An ORM is a great tool that facilitates developer productivity, but productivity comes at the expense of degraded performance in some scenarios. In a real-world cloud app you won't be making a choice between using EF or using ADO.NET directly -- you'll use both. Most of the time when you're writing code that works with the database, getting maximum performance is not critical and you can take advantage of the simplified coding and testing that you get with the Entity Framework. In situations where the EF overhead would cause unacceptable performance, you can write and execute your own queries using ADO.NET, ideally by calling stored procedures.

Whatever method you use to access the database, you want to minimize "chattiness" as much as possible. In other words, if you can get all the data you need in one larger query result set rather than dozens or hundreds of smaller ones, that's usually preferable. For example, if you need to list students and the courses they're enrolled in,

it's usually better to get all of the data in one join query rather than getting the students in one query and executing separate queries for each student's courses.

SQL databases and the Entity Framework in the Fix It app

In the Fix It app the `FixItContext` class, which derives from the Entity Framework `DbContext` class, identifies the database and specifies the tables in the database. The context specifies an entity set (table) for tasks, and the code passes in to the context the connection string name. That name refers to a connection string that is defined in the Web.config file.

```
public class MyFixItContext : DbContext
{
    public MyFixItContext()
        : base("name=appdb")
    {
    }

    public DbSet<MyFixIt.Persistence.FixItTask> FixItTasks { get; set; }
}
```

The connection string in the *Web.config* file is named appdb (here pointing to the local development database):

```
<connectionStrings>
    <add name="DefaultConnection" connectionString="Data Source=(LocalDb)\v11.0;Initial Catalog=aspnet-
MyFixIt-20130604091232_4;Integrated Security=True" providerName="System.Data.SqlClient" />
    <add name="appdb" connectionString="Data Source=(localdb)\v11.0; Initial Catalog=MyFixItContext-
20130604091609_11;Integrated Security=True; MultipleActiveResultSets=True"
providerName="System.Data.SqlClient" />
  </connectionStrings>
```

The Entity Framework creates a *FixItTasks* table based on the properties included in the `FixItTask` entity class. This is a simple POCO (Plain Old CLR Object) class, which means it doesn't inherit from or have any dependencies on the Entity Framework. But Entity Framework knows how to create a table based on it and execute CRUD (create-read-update-delete) operations with it.

```
public class FixItTask
{
    public int FixItTaskId  { get; set; }
    public string CreatedBy { get; set; }
    [Required]
    public string Owner     { get; set; }
    [Required]
    public string Title     { get; set; }
    public string Notes     { get; set; }
    public string PhotoUrl  { get; set; }
    public bool IsDone      { get; set; }
}
```

The Fix It app includes a repository interface that it uses for CRUD operations working with the data store.

```
public interface IFixItTaskRepository
{
    Task<List<FixItTask>> FindOpenTasksByOwnerAsync(string userName);
    Task<List<FixItTask>> FindTasksByCreatorAsync(string userName);

    Task<MyFixIt.Persistence.FixItTask> FindTaskByIdAsync(int id);

    Task CreateAsync(FixItTask taskToAdd);
    Task UpdateAsync(FixItTask taskToSave);
    Task DeleteAsync(int id);
}
```

Notice that the repository methods are all async, so all data access can be done in a completely asynchronous way.

The repository implementation calls Entity Framework async methods to work with the data, including LINQ queries as well as for insert, update, and delete operations. Here's an example of the code for looking up a Fix It task.

```
public async Task<FixItTask> FindTaskByIdAsync(int id)
{
    FixItTask fixItTask = null;
    Stopwatch timespan = Stopwatch.StartNew();

    try
    {
        fixItTask = await db.FixItTasks.FindAsync(id);

        timespan.Stop();
        log.TraceApi("SQL Database", "FixItTaskRepository.FindTaskByIdAsync", timespan.Elapsed, "id={0}",
id);
    }
    catch(Exception e)
    {
        log.Error(e, "Error in FixItTaskRepository.FindTaskByIdAsynx(id={0})", id);
    }

    return fixItTask;
}
```

You'll notice there's also some timing and error logging code here, we'll look at that later in the Monitoring and Telemetry chapter.

Choosing SQL Database (PaaS) versus SQL Server in a VM (IaaS) in

Azure

A nice thing about SQL Server and Azure SQL Database is that the core programming model for both of them is identical. You can use most of the same skills in both environments. You can even use a SQL Server database in development and a SQL Database instance in the cloud, which is how the Fix It app is set up.

As an alternative, you can run the same SQL Server in the cloud that you run on-premises by installing it on IaaS VMs. For some legacy applications, running SQL Server in a VM might be a better solution. Because a SQL Server database runs on a dedicated VM, it has more resources available to it than a SQL Database database that runs on a shared server. That means a SQL Server database can be larger and still perform well. In general, the smaller the database size and table size, the better the use case works for SQL Database (PaaS).

Here are some guidelines on how to choose between the two models.

AZURE SQL DATABASE (PAAS)	SQL SERVER IN A VIRTUAL MACHINE (IAAS)
Pros - You don't have to create or manage VMs, update or patch OS or SQL; Azure does that for you. - Built-in High Availability, with a database-level SLA. - Low total cost of ownership (TCO) because you pay only for what you use (no license required). - Good for handling large numbers of smaller databases (<=500 GB each). - Easy to dynamically create new databases to enable scale-out.	***Pros*** - Feature-compatible with on-premises SQL Server. - Can implement SQL Server High Availability via AlwaysOn in 2+ VMs, with VM-level SLA. - You have complete control over how SQL is managed. - Can re-use SQL licenses you already own, or pay by the hour for one. - Good for handling fewer but larger (1 TB+) databases.
Cons - Some feature gaps compared to on-premises SQL Server (lack of CLR integration, TDE, compression support, SQL Server Reporting Services, etc.) - Database size limit of 500GB.	***Cons*** - Updates/patches (OS and SQL) are your responsibility - Creation and management of DBs are your responsibility - Disk IOPS (input/output operations per second) limited to about 8000 (via 16 data drives).

If you want to use SQL Server in a VM, you can use your own SQL Server license, or you can pay for one by the hour. For example, in the portal or via the REST API you can create a new VM using a SQL Server image.

When you create a VM with a SQL Server image, we pro-rate the SQL Server license cost by the hour based on your usage of the VM. If you have a project that's only going to run for a couple of months, it's cheaper to pay by the hour. If you think your project is going to last for years, it's cheaper to buy the license the way you normally do.

Summary

Cloud computing makes it practical to mix and match data storage approaches to best fit the needs of your application. If you're building a new application, think carefully about the questions listed here in order to pick approaches that will continue to work well when your application grows. The next chapter will explain some partitioning strategies that you can use to combine multiple data storage approaches.

Data Partitioning Strategies (Building Real-World Cloud Apps with Azure)

2/20/2020 • 7 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the series, see the first chapter.

Earlier we saw how easy it is to scale the web tier of a cloud application, by adding and removing web servers. But if they're all hitting the same data store, your application's bottleneck moves from the front-end to the back-end, and the data tier is the hardest to scale. In this chapter we look at how you can make your data tier scalable by partitioning data into multiple relational databases, or by combining relational database storage with other data storage options.

Setting up a partitioning scheme is best done up front for the same reason mentioned earlier: it's very difficult to change your data storage strategy after an app is in production. If you think hard up front about different approaches, you can avoid having a "Twitter moment" when your app crashes or goes down for a long time while you reorganize your app's data and data access code.

The three Vs of data storage

In order to determine whether you need a partitioning strategy and what it should be, consider three questions about your data:

- Volume – How much data will you ultimately store? A couple gigabytes? A couple hundred gigabytes? Terabytes? Petabytes?
- Velocity – What is the rate at which your data will grow? Is it an internal app that isn't generating a lot of data? An external app that customers will be uploading images and videos into?
- Variety – What type of data will you store? Relational, images, key-value pairs, social graphs?

If you think you're going to have a lot of volume, velocity, or variety, you have to carefully consider what kind of partitioning scheme will best enable your app to scale efficiently and effectively as it grows, and to ensure you don't run into any bottlenecks.

There are basically three approaches to partitioning:

- Vertical partitioning
- Horizontal partitioning
- Hybrid partitioning

Vertical partitioning

Vertical portioning is like splitting up a table by columns: one set of columns goes into one data store, and another set of columns goes into a different data store.

For example, suppose my app stores data about people, including images:

First Name	Last Name	Email	Thumbnail	Photo
David	Alexander	davida@contoso.com	3kb	3MB
Jarred	Carlson	jaredc@contosco.com	3kb	3MB
Sue	Charles	suec@contosco.com	3kb	3MB
Simon	Mitchel	simonm@contoso.com	3kb	3MB
Richard	Zeng	richard@contosco.com	3kb	3MB

When you represent this data as a table and look at the different varieties of data, you can see that the three columns on the left have string data that can be efficiently stored by a relational database, while the two columns on the right are essentially byte arrays that come from image files. It's possible to store image file data in a relational database, and a lot of people do that because they don't want to save the data to the file system. They might not have a file system capable of storing the required volumes of data or they might not want to manage a separate back-up and restore system. This approach works well for on-premises databases and for small amounts of data in cloud databases. In the on-premises environment, it might be easier to just let the DBA take care of everything.

But in a cloud database, storage is relatively expensive, and a high volume of images could make the size of the database grow beyond the limits at which it can operate efficiently. You can address these problems by partitioning the data vertically, which means you choose the most appropriate data store for each column in your table of data. What might work best for this example is to put the string data in a relational database and the images in Blob storage.

Storing images in Blob storage instead of a database is more practical in the cloud than in an on-premises environment because you don't have to worry about setting up file servers or managing back-up and restore of data stored outside of the relational database: all that is handled for you automatically by the Blob storage service.

This is the partitioning approach we implemented in the Fix It app, and we'll look at the code for that in the Blob storage chapter. Without this partitioning scheme, and assuming an average image size of 3 megabytes, the Fix It app would only be able to store about 40,000 tasks before hitting the maximum database size of 150 gigabytes. After removing the images, the database can store 10 times as many tasks; you can go much longer before you have to think about implementing a horizontal partitioning scheme. And as the app scales, your expenses grow more slowly because the bulk of your storage needs are going into very inexpensive Blob storage.

Horizontal partitioning (sharding)

Horizontal portioning is like splitting up a table by rows: one set of rows goes into one data store, and another set of rows goes into a different data store.

Given the same set of data, another option would be to store different ranges of customer names in different databases.

You want to be very careful about your sharding scheme to make sure that data is evenly distributed in order to avoid hot spots. This simple example using the first letter of the last name doesn't meet that requirement, because a lot of people have last names that start with certain common letters. You'd hit table size limitations earlier than you might expect because some databases would get very large while most would remain small.

A down side of horizontal partitioning is that it might be hard to do queries across all of the data. In this example, a query would have to draw from up to 26 different databases to get all of the data stored by the app.

Hybrid partitioning

You can combine vertical and horizontal partitioning. For example, in the example data you could store the images in Blob storage and horizontally partition the string data.

Partitioning a production application

Conceptually it's easy to see how a partitioning scheme would work, but any partitioning scheme does increase code complexity and introduces many new complications that you have to deal with. If you're moving images to blob storage, what do you do when the storage service is down? How do you handle blob security? What happens if the database and blob storage get out of sync? If you're sharding, how will you handle querying across all of the databases?

The complications are manageable so long as you're planning for them before you go to production. Many people who didn't do that wish they had later. On average our Customer Advisory Team (CAT) team gets panicked phone calls about once a month from customers whose apps are taking off in a really big way, and they didn't do this planning. And they say something like: "Help! I put everything in a single data store, and in 45 days I'm going to run out of space on it!" And if you have a lot of business logic built into how you access your data store and you have customers who are using your app, there's no good time to go down for a day while you migrate. We end up going through herculean efforts to help the customer partition their data on the fly with no down time. It's very

exciting and very scary, and not something you want to be involved in if you can avoid it! Thinking about this up front and integrating it into your app will make your life a lot easier if the app grows later.

Summary

An effective partitioning scheme can enable your cloud app to scale to petabytes of data in the cloud without bottlenecks. And you don't have to pay up front for massive machines or extensive infrastructure as you might if you were running the app in an on-premises data center. In the cloud you can incrementally add capacity as you need it, and you're only paying for as much as you're using when you use it.

In the next chapter we'll see how the Fix It app implements vertical partitioning by storing images in Blob storage.

Resources

For more information about partitioning strategies, see the following resources.

Documentation:

- Best Practices for the Design of Large-Scale Services on Windows Azure Cloud Services. White paper by Mark Simms and Michael Thomassy.
- Microsoft Patterns and Practices - Cloud Design Patterns. See Data Partitioning guidance, Sharding pattern.

Videos:

- FailSafe: Building Scalable, Resilient Cloud Services. Nine-part series by Ulrich Homann, Marc Mercuri, and Mark Simms. Presents high-level concepts and architectural principles in a very accessible and interesting way, with stories drawn from Microsoft Customer Advisory Team (CAT) experience with actual customers. See the partitioning discussion in episode 7.
- Building Big: Lessons learned from Windows Azure customers - Part I. Mark Simms discusses partitioning schemes, sharding strategies, how to implement sharding, and SQL Database Federations, starting at 19:49. Similar to the Failsafe series but goes into more how-to details.

Sample code:

- Cloud Service Fundamentals in Windows Azure. Sample application that includes a sharded database. For a description of the sharding scheme implemented, see DAL – Sharding of RDBMS on the Windows Azure blog.

Unstructured Blob Storage (Building Real-World Cloud Apps with Azure)

2/20/2020 • 10 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

In the previous chapter we looked at partitioning schemes and explained how the Fix It app stores images in the Azure Storage Blob service, and other task data in Azure SQL Database. In this chapter we go deeper into the Blob service and show how it's implemented in Fix It project code.

What is Blob storage?

The Azure Storage Blob service provides a way to store files in the cloud. The Blob service has a number of advantages over storing files in a local network file system:

- It's highly scalable. A single Storage account can store hundreds of terabytes, and you can have multiple Storage accounts. Some of the biggest Azure customers store hundreds of petabytes. Microsoft SkyDrive uses blob storage.
- It's durable. Every file you store in the Blob service is automatically backed up.
- It provides high availability. The SLA for Storage promises 99.9% or 99.99% uptime, depending on which geo-redundancy option you choose.
- It's a platform-as-a-service (PaaS) feature of Azure, which means you just store and retrieve files, paying only for the actual amount of storage you use, and Azure automatically takes care of setting up and managing all of the VMs and disk drives required for the service.
- You can access the Blob service by using a REST API or by using a programming language API. SDKs are available for .NET, Java, Ruby, and others.
- When you store a file in the Blob service, you can easily make it publicly available over the Internet.
- You can secure files in the Blob service so they can accessed only by authorized users, or you can provide temporary access tokens that makes them available to someone only for a limited period of time.

Anytime you're building an app for Azure and you want to store a lot of data that in an on-premises environment would go in files -- such as images, videos, PDFs, spreadsheets, etc. -- consider the Blob service.

Creating a Storage account

To get started with the Blob service you create a Storage account in Azure. In the portal, click **New** -- **Data Services** -- **Storage** -- **Quick Create**, and then enter a URL and a data center location. The data center location should be the same as your web app.

You pick the primary region where you want to store the content, and if you choose the geo-replication option, Azure creates replicas of all your data in a different data center in another region of the country. For example, if you choose the Western US data center, when you store a file it goes to the Western US data center, but in the background Azure also copies it to one of the other US data centers. If a disaster happens in one region of the country, your data is still safe.

Azure won't replicate data across geo-political boundaries: if your primary location is in the U.S., your files are only replicated to another region within the U.S.; if your primary location is Australia, your files are only replicated to another data center in Australia.

Of course, you can also create a Storage account by executing commands from a script, as we saw earlier. Here's a Windows PowerShell command to create a Storage account:

```
# Create a new storage account
New-AzureStorageAccount -StorageAccountName $Name -Location $Location -Verbose
```

Once you have a Storage account, you can immediately start storing files in the Blob service.

Using Blob storage in the Fix It app

The Fix It app enables you to upload photos.

When you click **Create the FixIt**, the application uploads the specified image file and stores it in the Blob service.

Set up the Blob container

In order to store a file in the Blob service you need a *container* to store it in. A Blob service container corresponds to a file system folder. The environment creation scripts that we reviewed in the Automate Everything chapter create the Storage account, but they don't create a container. So the purpose of the `CreateAndConfigure` method of the `PhotoService` class is to create a container if it doesn't already exist. This method is called from the `Application_Start` method in *Global.asax*.

```
public async void CreateAndConfigureAsync()
{
    try
    {
        CloudStorageAccount storageAccount = StorageUtils.StorageAccount;

        // Create a blob client and retrieve reference to images container
        CloudBlobClient blobClient = storageAccount.CreateCloudBlobClient();
        CloudBlobContainer container = blobClient.GetContainerReference("images");

        // Create the "images" container if it doesn't already exist.
        if (await container.CreateIfNotExistsAsync())
        {
            // Enable public access on the newly created "images" container
            await container.SetPermissionsAsync(
                new BlobContainerPermissions
                {
                    PublicAccess =
                        BlobContainerPublicAccessType.Blob
                });

            log.Information("Successfully created Blob Storage Images Container and made it public");
        }
    }
    catch (Exception ex)
    {
        log.Error(ex, "Failure to Create or Configure images container in Blob Storage Service");
    }
}
```

The storage account name and access key are stored in the `appSettings` collection of the *Web.config* file, and code in the `StorageUtils.StorageAccount` method uses those values to build a connection string and establish a connection:

```
string account = CloudConfigurationManager.GetSetting("StorageAccountName");
string key = CloudConfigurationManager.GetSetting("StorageAccountAccessKey");
string connectionString = String.Format("DefaultEndpointsProtocol=https;AccountName={0};AccountKey={1}",
account, key);
return CloudStorageAccount.Parse(connectionString);
```

The `CreateAndConfigureAsync` method then creates an object that represents the Blob service, and an object that represents a container (folder) named "images" in the Blob service:

```
CloudBlobClient blobClient = storageAccount.CreateCloudBlobClient();
CloudBlobContainer container = blobClient.GetContainerReference("images");
```

If a container named "images" doesn't exist yet -- which will be true the first time you run the app against a new storage account -- the code creates the container and sets permissions to make it public. (By default, new blob containers are private and are accessible only to users who have permission to access your storage account.)

```
if (await container.CreateIfNotExistsAsync())
{
    // Enable public access on the newly created "images" container
    await container.SetPermissionsAsync(
        new BlobContainerPermissions
        {
            PublicAccess =
                BlobContainerPublicAccessType.Blob
        });

    log.Information("Successfully created Blob Storage Images Container and made it public");
}
```

Store the uploaded photo in Blob storage

To upload and save the image file, the app uses an `IPhotoService` interface and an implementation of the interface in the `PhotoService` class. The *PhotoService.cs* file contains all of the code in the Fix It app that communicates with the Blob service.

The following MVC controller method is called when the user clicks **Create the FixIt**. In this code, `photoService` refers to an instance of the `PhotoService` class, and `fixittask` refers to an instance of the `FixItTask` entity class that stores data for a new task.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Create([Bind(Include =
"FixItTaskId,CreatedBy,Owner,Title,Notes,PhotoUrl,IsDone")]FixItTask fixittask, HttpPostedFileBase photo)
{
    if (ModelState.IsValid)
    {
        fixittask.CreatedBy = User.Identity.Name;
        fixittask.PhotoUrl = await photoService.UploadPhotoAsync(photo);
        await fixItRepository.CreateAsync(fixittask);
        return RedirectToAction("Success");
    }

    return View(fixittask);
}
```

The `UploadPhotoAsync` method in the `PhotoService` class stores the uploaded file in the Blob service and returns a URL that points to the new blob.

```
public async Task<string> UploadPhotoAsync(HttpPostedFileBase photoToUpload)
{
    if (photoToUpload == null || photoToUpload.ContentLength == 0)
    {
        return null;
    }

    string fullPath = null;
    Stopwatch timespan = Stopwatch.StartNew();

    try
    {
        CloudStorageAccount storageAccount = StorageUtils.StorageAccount;

        // Create the blob client and reference the container
        CloudBlobClient blobClient = storageAccount.CreateCloudBlobClient();
        CloudBlobContainer container = blobClient.GetContainerReference("images");

        // Create a unique name for the images we are about to upload
        string imageName = String.Format("task-photo-{0}{1}",
            Guid.NewGuid().ToString(),
            Path.GetExtension(photoToUpload.FileName));

        // Upload image to Blob Storage
        CloudBlockBlob blockBlob = container.GetBlockBlobReference(imageName);
        blockBlob.Properties.ContentType = photoToUpload.ContentType;
        await blockBlob.UploadFromStreamAsync(photoToUpload.InputStream);

        // Convert to be HTTP based URI (default storage path is HTTPS)
        var uriBuilder = new UriBuilder(blockBlob.Uri);
        uriBuilder.Scheme = "http";
        fullPath = uriBuilder.ToString();

        timespan.Stop();
        log.TraceApi("Blob Service", "PhotoService.UploadPhoto", timespan.Elapsed, "imagepath={0}",
fullPath);
    }
    catch (Exception ex)
    {
        log.Error(ex, "Error upload photo blob to storage");
    }

    return fullPath;
}
```

As in the `CreateAndConfigure` method, the code connects to the storage account and creates an object that represents the "images" blob container, except here it assumes the container already exists.

Then it creates a unique identifier for the image about to be uploaded, by concatenating a new GUID value with the file extension:

```
string imageName = String.Format("task-photo-{0}{1}",
    Guid.NewGuid().ToString(),
    Path.GetExtension(photoToUpload.FileName));
```

The code then uses the blob container object and the new unique identifier to create a blob object, sets an attribute on that object indicating what kind of file it is, and then uses the blob object to store the file in blob storage.

```
CloudBlockBlob blockBlob = container.GetBlockBlobReference(imageName);
blockBlob.Properties.ContentType = photoToUpload.ContentType;
blockBlob.UploadFromStream(photoToUpload.InputStream);
```

Finally, it gets a URL that references the blob. This URL will be stored in the database and can be used in Fix It web pages to display the uploaded image.

```
fullPath = String.Format("http://{0}{1}", blockBlob.Uri.DnsSafeHost, blockBlob.Uri.AbsolutePath);
```

This URL is stored in the database as one of the columns of the FixItTask table.

```
public class FixItTask
{
    public int FixItTaskId  { get; set; }
    public string CreatedBy { get; set; }
    [Required]
    public string Owner     { get; set; }
    [Required]
    public string Title     { get; set; }
    public string Notes     { get; set; }
    public string PhotoUrl  { get; set; }
    public bool IsDone      { get; set; }
}
```

With only the URL in the database, and images in Blob storage, the Fix It app keeps the database small, scalable, and inexpensive, while the images are stored where storage is cheap and capable of handling terabytes or petabytes. One storage account can store hundreds of terabytes of Fix It photos, and you only pay for what you use. So you can start off small paying 9 cents for the first gigabyte, and add more images for pennies per additional gigabyte.

Display the uploaded file

The Fix It application displays the uploaded image file when it displays details for a task.

To display the image, all the MVC view has to do is include the `PhotoUrl` value in the HTML sent to the browser. The web server and the database are not using cycles to display the image, they are only serving up a few bytes to the image URL. In the following Razor code, `Model` refers to an instance of the `FixItTask` entity class.

```
<fieldset>
<legend>@Html.DisplayFor(model => model.Title)</legend>
<dl>
    <dt>Opened By</dt>
    <dd>@Html.DisplayFor(model => model.CreatedBy)</dd>
                <br />
    <dt>@Html.DisplayNameFor(model => model.Notes)</dt>
    <dd>@Html.DisplayFor(model => model.Notes)</dd>
                <br />
                @if(Model.PhotoUrl != null) {
        <dd><img src="@Model.PhotoUrl" title="@Model.Title" /></dd>
                }
</dl>
</fieldset>
```

If you look at the HTML of the page that displays, you see the URL pointing directly to the image in blob storage, something like this:

```
<fieldset>
<legend>Brush the dog again</legend>
<dl>
    <dt>Opened By</dt>
    <dd>Tom</dd>
                <br />
    <dt>Notes</dt>
    <dd>Another dog brushing task</dd>
                <br />
    <dd>
<img src="http://storageaccountname.blob.core.windows.net/images/task-photo-312dd635-ba87-4542-8b15-
767032c55f4e.jpg"
           title="Brush the dog again" />
    </dd>
</dl>
</fieldset>
```

Summary

You've seen how the Fix It app stores images in the Blob service and only image URLs in the SQL database. Using the Blob service keeps the SQL database much smaller than it otherwise would be, makes it possible to scale up to an almost unlimited number of tasks, and can be done without writing a lot of code.

You can have hundreds of terabytes in a storage account, and the storage cost is much less expensive than SQL Database storage, starting at about 3 cents per gigabyte per month plus a small transaction charge. And keep in mind that you're not paying for the maximum capacity but only for the amount you actually store, so your app is ready to scale but you're not paying for all that extra capacity.

In the next chapter we'll talk about the importance of making a cloud app capable of gracefully handling failures.

Design to Survive Failures (Building Real-World Cloud Apps with Azure)

2/20/2020 • 11 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

One of the things you have to think about when you build any type of application, but especially one that will run in the cloud where lots of people will be using it, is how to design the app so that it can gracefully handle failures and continue to deliver value as much as possible. Given enough time, things are going to go wrong in any environment or any software system. How your app handles those situations determines how upset your customers will get and how much time you have to spend analyzing and fixing problems.

Types of failures

There are two basic categories of failures that you'll want to handle differently:

- Transient, self-healing failures such as intermittent network connectivity issues.
- Enduring failures that require intervention.

For transient failures, you can implement a retry policy to ensure that most of the time the app recovers quickly and automatically. Your customers might notice slightly longer response time, but otherwise they won't be affected. We'll show some ways to handle these errors in the Transient Fault Handling chapter.

For enduring failures, you can implement monitoring and logging functionality that notifies you promptly when issues arise and that facilitates root cause analysis. We'll show some ways to help you stay on top of these kinds of errors in the Monitoring and Telemetry chapter.

Failure scope

You also have to think about failure scope – whether a single machine is affected, a whole service such as SQL Database or Storage, or an entire region.

Machine failures

In Azure, a failed server is automatically replaced by a new one, and a well-designed cloud app recovers from this kind of failure automatically and quickly. Earlier we stressed the scalability benefits of a stateless web tier, and ease of recovery from a failed server is another benefit of statelessness. Ease of recovery is also one of the benefits of platform-as-a-service (PaaS) features such as SQL Database and Azure App Service Web Apps. Hardware failures are rare, but when they occur these services handle them automatically; you don't even have to write code to handle machine failures when you're using one of these services.

Service failures

Cloud apps typically use multiple services. For example, the Fix It app uses the SQL Database service, the Storage service, and the web app is deployed to Azure App Service. What will your app do if one of the services you depend on fails? For some service failures a friendly "sorry, try again later" message might be the best you can do. But in many scenarios you can do better. For example, when your back-end data store is down, you can accept user input, display "your request has been received," and store the input someplace else temporarily; then when the service you need is operational again, you can retrieve the input and process it.

The Queue-centric Work Pattern chapter shows one way to handle this scenario. The Fix It app stores tasks in SQL Database, but it doesn't have to quit working when SQL Database is down. In that chapter we'll see how to store user input for a task in a queue, and use a worker process to read the queue and update the task. If SQL is down, the ability to create Fix It tasks is unaffected; the worker process can wait and process new tasks when SQL Database is available.

Region failures

Entire regions may fail. A natural disaster might destroy a data center, it might get flattened by a meteor, the trunk line into the datacenter could be cut by a farmer burying a cow with a backhoe, etc. If your app is hosted in the stricken datacenter what do you do? It's possible to set up your app in Azure to run in multiple regions simultaneously so that if there's a disaster in one, you continue running in another region. Such failures are extremely rare occurrences, and most apps don't jump through the hoops necessary to ensure uninterrupted service through failures of this sort. See the Resources section at the end of the chapter for information about how to keep your app available even through a region failure.

A goal of Azure is to make handling all of these kinds of failures a lot easier, and you'll see some examples of how we're doing that in the following chapters.

SLAs

People often hear about service-level agreements (SLAs) in the cloud environment. Basically these are promises that companies make about how reliable their service is. A 99.9% SLA means you should expect the service to be working correctly 99.9% of the time. That's a fairly typical value for an SLA and it sounds like a very high number, but you might not realize how much down time .1% actually amounts to. Here's a table that shows how much downtime various SLA percentages amount to over a year, a month, and a week.

Availability %	Downtime per year	Downtime per month*	Downtime per week
90% ("one nine")	36.5 days	72 hours	16.8 hours
99% ("two nines")	3.65 days	7.20 hours	1.68 hours
99.9% ("three nines")	8.76 hours	43.2 minutes	10.1 minutes
99.99% ("four nines")	52.56 minutes	4.32 minutes	1.01 minutes
99.999% ("five nines")	5.26 minutes	25.9 seconds	6.05 seconds
99.9999% ("six nines")	31.5 seconds	2.59 seconds	0.605 seconds

So a 99.9% SLA means your service could be down 8.76 hours a year or 43.2 minutes a month. That's more down time than most people realize. So as a developer you want to be aware that a certain amount of down time is possible and handle it in a graceful way. At some point someone is going to be using your app, and a service is going to be down, and you want to minimize the negative impact of that on the customer.

One thing you should know about an SLA is what time-frame it refers to: does the clock get reset every week,

every month, or every year? In Azure we reset the clock every month, which is better for you than a yearly SLA, since a yearly SLA could hide bad months by offsetting them with a series of good months.

Of course we always aspire to do better than the SLA; usually you'll be down much less than that. The promise is that if we're ever down for longer than the maximum down time you can ask for money back. The amount of money you get back probably wouldn't fully compensate you for the business impact of the excess down time, but that aspect of the SLA acts as an enforcement policy and lets you know that we do take it very seriously.

Composite SLAs

An important thing to think about when you're looking at SLAs is the impact of using multiple services in an app, with each service having a separate SLA. For example, the Fix It app uses Azure App Service Web Apps, Azure Storage, and SQL Database. Here are their SLA numbers as of the date this e-book is being written in December, 2013:

What is the maximum down time you would expect for the app based on these service SLAs? You might think that your down time would be equal to the worst SLA percentage, or 99.9% in this case. That would be true if all three services always failed at the same time, but that isn't necessarily what actually happens. Each service may fail independently at different times, so you have to calculate the composite SLA by multiplying the individual SLA numbers.

So your app could be down not just 43.2 minutes a month but 3 times that amount, 108 minutes a month – and still be within the Azure SLA limits.

This issue is not unique to Azure. We actually provide the best cloud SLAs of any cloud service available, and you'll have similar issues to deal with if you use any vendor's cloud services. What this highlights is the importance of thinking about how you can design your app to handle the inevitable service failures gracefully, because they might happen often enough to impact your customers or users.

Cloud SLAs compared to enterprise down-time experience

People sometimes say, "In my enterprise app I never have these problems." If you ask how much down time a month they actually have, they usually say, "Well, it happens occasionally." And if you ask how often, they admit that "Sometimes we do need to back up or install a new server or update software." Of course, that counts as down time. Most enterprise apps unless they are especially mission-critical are actually down for more than the amount of time allowed by our service SLAs. But when it's your server and your infrastructure and you're responsible for it and in control of it, you tend to feel less angst about down times. In a cloud environment you're dependent on someone else and you don't know what's going on, so you might tend to get more worried about it.

When an enterprise achieves a greater up-time percentage than you get from a cloud SLA, they do it by spending a lot more money on hardware. A cloud service could do that but would have to charge much more for its services. Instead, you take advantage of a cost-effective service and design your software so that the inevitable

failures cause minimum disruption to your customers. Your job as a cloud app designer is not so much to avoid failure as to avoid catastrophe, and you do that by focusing on software, not on hardware. Whereas enterprise apps strive to maximize mean time between failures, cloud apps strive to minimize mean time to recover.

Not all cloud services have SLAs

Be aware also that not every cloud service even has an SLA. If your app is dependent on a service with no up-time guarantee, you could be down far longer than you might imagine. For example, if you enable log-in to your site using a social provider such as Facebook or Twitter, check with the service provider to find out if there is an SLA, and you might find out there isn't one. But if the authentication service goes down or is unable to support the volume of requests you throw at it, your customers are locked out of your app. You could be down for days or longer. The creators of one new app expected hundreds of millions of downloads and took a dependency on Facebook authentication – but didn't talk to Facebook before going live and discovered too late that there was no SLA for that service.

Not all downtime counts toward SLAs

Some cloud services may deliberately deny service if your app over-uses them. This is called *throttling*. If a service has an SLA, it should state the conditions under which you might be throttled, and your app design should avoid those conditions and react appropriately to the throttling if it happens. For example, if requests to a service start to fail when you exceed a certain number per second, you want to make sure automatic retries don't happen so fast that they cause the throttling to continue. We'll have more to say about throttling in the Transient Fault Handling chapter.

Summary

This chapter has tried to help you realize why a real world cloud app has to be designed to survive failures gracefully. Starting with the next chapter, the remaining patterns in this series go into more detail about some strategies you can use to do that:

- Have good monitoring and telemetry, so that you find out quickly about failures that require intervention, and you have sufficient information to resolve them.
- Handle transient faults by implementing intelligent retry logic, so that your app recovers automatically when it can and falls back to circuit breaker logic when it can't.
- Use distributed caching in order to minimize throughput, latency, and connection problems with database access.
- Implement loose coupling via the queue-centric work pattern, so that your app front end can continue to work when the back end is down.

Monitoring and Telemetry (Building Real-World Cloud Apps with Azure)

2/20/2020 • 18 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

A lot of people rely on customers to let them know when their application is down. That's not really a best practice anywhere, and especially not in the cloud. There's no guarantee of quick notification, and when you do get notified, you often get minimal or misleading data about what happened. With good telemetry and logging systems you can be aware of what's going on with your app, and when something does go wrong you find out right away and have helpful troubleshooting information to work with.

Buy or rent a telemetry solution

> **NOTE**
>
> This article was written before Application Insights was released. Application Insights is the preferred approach for telemetry solutions on Azure. See Set up Application Insights for your ASP.NET website for more information.

One of the things that's great about the cloud environment is that it's really easy to buy or rent your way to victory. Telemetry is an example. Without a lot of effort you can get a really good telemetry system up and running, very cost-effectively. There are a bunch of great partners that integrate with Azure, and some of them have free tiers – so you can get basic telemetry for nothing. Here are just a few of the ones currently available on Azure:

- New Relic
- AppDynamics
- Dynatrace

Microsoft System Center also includes monitoring features.

We'll quickly walk through setting up New Relic to show how easy it can be to use a telemetry system.

In the Azure management portal, sign up for the service. Click **New**, and then click **Store**. The **Choose an Add-on** dialog box appears. Scroll down and click **New Relic**.

Click the right arrow and choose the service tier you want. For this demo we'll use the free tier.

Click the right arrow, confirm the "purchase," and New Relic now shows up as an Add-on in the portal.

Click **Connection Info**, and copy the license key.

Go to the **Configure** tab for your web app in the portal, set **Performance Monitoring** to **Add-On**, and set the

Choose Add-On drop-down list to **New Relic**. Then click **Save**.

In Visual Studio, install the New Relic NuGet package in your app.

Deploy the app to Azure and start using it. Create a few Fix It tasks to provide some activity for New Relic to monitor.

Then go back to the **New Relic** page in the **Add-ons** tab of the portal and click **Manage**. The portal sends you to the New Relic management portal, using single sign-on for authentication so you don't have to enter your credentials again. The Overview page presents a variety of performance statistics. (Click the image to see the overview page full size.)

Here are just a few of the statistics you can see:

- Average response time at different times of day.

- Throughput rates (in requests per minute) at different times of day.

- Server CPU time spent handling different HTTP requests.

- CPU time spent in different parts of the application code:

Summary | **Trace details**

Expand performance problems Collapse all

Duration (ms)	Duration (%)	Segment	Drilldown	Timestamp
5,370	**100.00%**	**System.Web.HttpApplication.BeginRequest()**		0.000 s

Web external

- Information about where in the world or where in the U.S. web app traffic came from.

You can also set up reports and events. For example, you can say any time you start seeing errors, send an email to alert support staff to the problem.

New Relic is just one example of a telemetry system; you can get all of this from other services as well. The beauty of the cloud is that without having to write any code, and for minimal or no expense, you suddenly can get a lot more information about how your application is being used and what your customers are actually experiencing.

Log for insight

A telemetry package is a good first step, but you still have to instrument your own code. The telemetry service tells you when there's a problem and tells you what the customers are experiencing, but it may not give you a lot of insight into what's going on in your code.

You don't want to have to remote into a production server to see what your app is doing. That might be practical when you've got one server, but what about when you've scaled to hundreds of servers and you don't know which ones you need to remote into? Your logging should provide enough information that you never have to remote into production servers to analyze and debug problems. You should be logging enough information so that you can isolate issues solely through the logs.

Log in production

A lot of people turn on tracing in production only when there's a problem and they want to debug. This can introduce a substantial delay between the time you're aware of a problem and the time you get useful troubleshooting information about it. And the information you get might not be helpful for intermittent errors.

What we recommend in the cloud environment where storage is cheap is that you always leave logging on in production. That way when errors happen you already have them logged, and you have historical data that can help you analyze issues that develop over time or happen regularly at different times. You could automate a purge process to delete old logs, but you might find that it's more expensive to set up such a process than it is to keep the logs.

The added expense of logging is trivial compared to the amount of troubleshooting time and money you can save by having all of the information you need already available when something goes wrong. Then when someone tells you they had a random error sometime around 8:00 last night, but they don't remember the error, you can readily find out what the problem was.

For less than $4 a month you can keep 50 gigabytes of logs on hand, and the performance impact of logging is trivial so long as you keep one thing in mind -- in order to avoid performance bottlenecks, make sure your logging library is asynchronous.

Differentiate logs that inform from logs that require action

Logs are meant to INFORM (I want you to know something) or ACT (I want you to do something). Be careful to only write ACT logs for issues that genuinely require a person or an automated process to take action. Too many ACT logs will create noise, requiring too much work to sift through it all to find genuine issues. And if your ACT logs automatically trigger some action such as sending email to support staff, avoid letting thousands of such actions be triggered by a single issue.

In .NET System.Diagnostics tracing, logs can be assigned Error, Warning, Info, and Debug/Verbose level. You can differentiate ACT from INFORM logs by reserving the Error level for ACT logs and using the lower levels for INFORM logs.

Level	Context
Error	Always on in production. Any errors will trigger ACTION to resolve (automated or human). • Configuration issues • Application failure (cascading failure or critical service down)
Warning	Always on in production. Warnings will INFORM, and may signal potential ACTION • Timeouts or throttling in external service
Info	Always on in production. Info messages INFORM during diagnostics and troubleshooting
Debug (Verbose)	On during active debugging and troubleshooting on a case by case basis

Configure logging levels at run time

While it's worthwhile to have logging always on in production, another best practice is to implement a logging framework that enables you to adjust at run-time the level of detail that you're logging, without redeploying or restarting your application. For example when you use the tracing facility in `System.Diagnostics` you can create Error, Warning, Info, and Debug/Verbose logs. We recommend you always log Error, Warning, and Info logs in production, and you'll want to be able to dynamically add Debug/Verbose logging for troubleshooting on a case-by-case basis.

Web Apps in Azure App Service have built-in support for writing `System.Diagnostics` logs to the file system, Table storage, or Blob storage. You can select different logging levels for each storage destination, and you can change the logging level on the fly without restarting your application. The Blob storage support makes it easier to run HDInsight analysis jobs on your application logs, because HDInsight knows how to work with Blob storage directly.

Log Exceptions

Don't just put *exception.ToString()* in your logging code. That leaves out contextual information. In the case of SQL errors, it leaves out the SQL error number. For all exceptions, include context information, the exception itself, and inner exceptions to make sure that you are providing everything that will be needed for troubleshooting. For example, context information might include the server name, a transaction identifier, and a user name (but not the password or any secrets!).

If you rely on each developer to do the right thing with exception logging, some of them won't. To ensure that it gets done the right way every time, build exception handling right into your logger interface: pass the exception object itself to the logger class and log the exception data properly in the logger class.

Log calls to services

We highly recommend that you write a log every time your app calls out to a service, whether it's to a database or a REST API or any external service. Include in your logs not only an indication of success or failure but how long each request took. In the cloud environment you'll often see problems related to slow-downs rather than complete outages. Something that normally takes 10 milliseconds might suddenly start taking a second. When someone tells you your app is slow, you want to be able to look at New Relic or whatever telemetry service you have and validate their experience, and then you want to be able to look are your own logs to dive into the details of why it's slow.

Use an ILogger interface

What we recommend doing when you create a production application is to create a simple *ILogger* interface and stick some methods in it. This makes it easy to change the logging implementation later and not have to go through all your code to do it. We could be using the `System.Diagnostics.Trace` class throughout the Fix It app, but instead we're using it under the covers in a logging class that implements *ILogger*, and we make *ILogger* method calls throughout the app.

That way, if you ever want to make your logging richer, you can replace `System.Diagnostics.Trace` with whatever logging mechanism you want. For example, as your app grows you might decide that you want to use a more comprehensive logging package such as NLog or Enterprise Library Logging Application Block. (Log4Net is another popular logging framework but it doesn't do asynchronous logging.)

One possible reason for using a framework such as NLog is to facilitate dividing up logging output into separate high-volume and high-value data stores. That helps you to efficiently store large volumes of INFORM data that you don't need to execute fast queries against, while maintaining quick access to ACT data.

Semantic Logging

For a relatively new way to do logging that can produce more useful diagnostic information, see Enterprise Library Semantic Logging Application Block (SLAB). SLAB uses Event Tracing for Windows (ETW) and EventSource support in .NET 4.5 to enable you to create more structured and queryable logs. You define a different method for each type of event that you log, which enables you to customize the information you write. For example, to log a SQL Database error you might call a `LogSQLDatabaseError` method. For that kind of exception, you know a key piece of information is the error number, so you could include an error number parameter in the method signature and record the error number as a separate field in the log record you write. Because the number is in a separate field you can more easily and reliably get reports based on SQL error numbers than you could if you were just concatenating the error number into a message string.

Logging in the Fix It app

The ILogger interface

Here is the *ILogger* interface in the Fix It app.

```
public interface ILogger
{
    void Information(string message);
    void Information(string fmt, params object[] vars);
    void Information(Exception exception, string fmt, params object[] vars);

    void Warning(string message);
    void Warning(string fmt, params object[] vars);
    void Warning(Exception exception, string fmt, params object[] vars);

    void Error(string message);
    void Error(string fmt, params object[] vars);
    void Error(Exception exception, string fmt, params object[] vars);

    void TraceApi(string componentName, string method, TimeSpan timespan);
    void TraceApi(string componentName, string method, TimeSpan timespan, string properties);
    void TraceApi(string componentName, string method, TimeSpan timespan, string fmt, params object[] vars);
}
```

These methods enable you to write logs at the same four levels supported by *System.Diagnostics*. The TraceApi methods are for logging external service calls with information about latency. You could also add a set of methods for Debug/Verbose level.

The Logger implementation of the ILogger interface

The implementation of the interface is really simple. It basically just calls into the standard *System.Diagnostics* methods. The following snippet shows all three of the Information methods and one each of the others.

```
public class Logger : ILogger
{
    public void Information(string message)
    {
        Trace.TraceInformation(message);
    }

    public void Information(string fmt, params object[] vars)
    {
        Trace.TraceInformation(fmt, vars);
    }

    public void Information(Exception exception, string fmt, params object[] vars)
    {
        var msg = String.Format(fmt, vars);
        Trace.TraceInformation(string.Format(fmt, vars) + ";Exception Details={0}", exception.ToString());
    }

    public void Warning(string message)
    {
        Trace.TraceWarning(message);
    }

    public void Error(string message)
    {
        Trace.TraceError(message);
    }

    public void TraceApi(string componentName, string method, TimeSpan timespan, string properties)
    {
        string message = String.Concat("component:", componentName, ";method:", method, ";timespan:",
timespan.ToString(), ";properties:", properties);
        Trace.TraceInformation(message);
    }
}
```

Calling the ILogger methods

Every time code in the Fix It app catches an exception, it calls an *ILogger* method to log the exception details. And every time it makes a call to the database, Blob service, or a REST API, it starts a stopwatch before the call, stops the stopwatch when the service returns, and logs the elapsed time along with information about success or failure.

Notice that the log message includes the class name and method name. It's a good practice to make sure that log messages identify what part of the application code wrote them.

```
public class FixItTaskRepository : IFixItTaskRepository
{
    private MyFixItContext db = new MyFixItContext();
    private ILogger log = null;

    public FixItTaskRepository(ILogger logger)
    {
        log = logger;
    }

    public async Task<FixItTask> FindTaskByIdAsync(int id)
    {
        FixItTask fixItTask = null;
        Stopwatch timespan = Stopwatch.StartNew();

        try
        {
            fixItTask = await db.FixItTasks.FindAsync(id);

            timespan.Stop();
            log.TraceApi("SQL Database", "FixItTaskRepository.FindTaskByIdAsync", timespan.Elapsed, "id=
{0}", id);
        }
        catch(Exception e)
        {
            log.Error(e, "Error in FixItTaskRepository.FindTaskByIdAsynx(id={0})", id);
        }

        return fixItTask;
    }
```

So now for every time the Fix It app has made a call to SQL Database, you can see the call, the method that called it, and exactly how much time it took.

If you go browsing through the logs, you can see that the time database calls take is variable. That information could be useful: because the app logs all this you can analyze historical trends in how the database service is performing over time. For instance, a service might be fast most of the time but requests might fail or responses might slow down at certain times of day.

You can do the same thing for the Blob service – for every time the app uploads a new file, there's a log, and you can see exactly how long it took to upload each file.

It's just a couple extra lines of code to write every time you call a service, and now whenever someone says they ran into an issue, you know exactly what the issue was, whether it was an error, or even if it was just running slow. You can pinpoint the source of the problem without having to remote into a server or turn on logging after the error happens and hope to re-create it.

Dependency Injection in the Fix It app

You might wonder how the repository constructor in the example shown above gets the logger interface implementation:

```
public class FixItTaskRepository : IFixItTaskRepository
{
    private MyFixItContext db = new MyFixItContext();
    private ILogger log = null;

    public FixItTaskRepository(ILogger logger)
    {
        log = logger;
    }
```

To wire up the interface to the implementation the app uses dependency injection(DI) with AutoFac. DI enables you to use an object based on an interface in many places throughout your code and only have to specify in one place the implementation that gets used when the interface is instantiated. This makes it easier to change the implementation: for example, you might want to replace the System.Diagnostics logger with an NLog logger. Or for automated testing you might want to substitute a mock version of the logger.

The Fix It application uses DI in all of the repositories and all of the controllers. The constructors of the controller classes get an *ITaskRepository* interface the same way the repository gets a logger interface:

```
public class DashboardController : Controller
{
    private IFixItTaskRepository fixItRepository = null;

    public DashboardController(IFixItTaskRepository repository)
    {
        fixItRepository = repository;
    }
```

The app uses the AutoFac DI library to automatically provide *TaskRepository* and *Logger* instances for these constructors.

```
public class DependenciesConfig
{
    public static void RegisterDependencies()
    {
        var builder = new ContainerBuilder();

        builder.RegisterControllers(typeof(MvcApplication).Assembly);
        builder.RegisterType<Logger>().As<ILogger>().SingleInstance();

        builder.RegisterType<FixItTaskRepository>().As<IFixItTaskRepository>();
        builder.RegisterType<PhotoService>().As<IPhotoService>().SingleInstance();
        builder.RegisterType<FixItQueueManager>().As<IFixItQueueManager>();

        var container = builder.Build();
        DependencyResolver.SetResolver(new AutofacDependencyResolver(container));
    }
}
```

This code basically says that anywhere a constructor needs an *ILogger* interface, pass in an instance of the *Logger* class, and whenever it needs an *IFixItTaskRepository* interface, pass in an instance of the *FixItTaskRepository* class.

AutoFac is one of many dependency injection frameworks that you can use. Another popular one is Unity, which is recommended and supported by Microsoft Patterns and Practices.

Built-in logging support in Azure

Azure supports the following kinds of logging for Web Apps in Azure App Service:

- System.Diagnostics tracing (you can turn on and off and set levels on the fly without restarting the site).
- Windows Events.
- IIS Logs (HTTP/FREB).

Azure supports the following kinds of logging in Cloud Services:

- System.Diagnostics tracing.
- Performance counters.
- Windows Events.
- IIS Logs (HTTP/FREB).
- Custom directory monitoring.

The Fix It app uses System.Diagnostics tracing. All you need to do to enable System.Diagnostics logging in an web app is flip a switch in the portal or call the REST API. In the portal, click the **Configuration** tab for your site, and scroll down to see the **Application Diagnostics** section. You can turn logging on or off and select the logging level you want. You can have Azure write the logs to the file system or to a storage account.

After you enable logging in Azure, you can see logs in the Visual Studio Output window as they are created.

You can also have logs written to your storage account and view them with any tool that can access the Azure Storage Table service, such as **Server Explorer** in Visual Studio or Azure Storage Explorer.

Summary

It's really simple to implement an out-of-the-box telemetry system, instrument logging in your own code, and configure logging in Azure. And when you have production issues, the combination of a telemetry system and custom logs will help you resolve problems quickly before they become major issues for your customers.

In the next chapter we'll look at how to handle transient errors so they don't become production issues that you have to investigate.

Transient Fault Handling (Building Real-World Cloud Apps with Azure)

2/20/2020 • 7 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

When you're designing a real world cloud app, one of the things you have to think about is how to handle temporary service interruptions. This issue is uniquely important in cloud apps because you're so dependent on network connections and external services. You can frequently get little glitches that are typically self-healing, and if you aren't prepared to handle them intelligently, they'll result in a bad experience for your customers.

Causes of transient failures

In the cloud environment you'll find that failed and dropped database connections happen periodically. That's partly because you're going through more load balancers compared to the on-premises environment where your web server and database server have a direct physical connection. Also, sometimes when you're dependent on a multi-tenant service you'll see calls to the service get slower or time out because someone else who uses the service is hitting it heavily. In other cases you might be the user who is hitting the service too frequently, and the service deliberately throttles you – denies connections – in order to prevent you from adversely affecting other tenants of the service.

Use smart retry/back-off logic to mitigate the effect of transient failures

Instead of throwing an exception and displaying a not available or error page to your customer, you can recognize errors that are typically transient, and automatically retry the operation that resulted in the error, in hopes that before long you'll be successful. Most of the time the operation will succeed on the second try, and you'll recover from the error without the customer ever having been aware that there was a problem.

There are several ways you can implement smart retry logic.

- The Microsoft Patterns & Practices group has a Transient Fault Handling Application Block that does everything for you if you're using ADO.NET for SQL Database access (not through Entity Framework). You just set a policy for retries – how many times to retry a query or command and how long to wait between tries – and wrap your SQL code in a *using* block.

```
public void HandleTransients()
{
    var connStr = "some database";
    var _policy = RetryPolicy.Create < SqlAzureTransientErrorDetectionStrategy(
        retryCount: 3,
        retryInterval: TimeSpan.FromSeconds(5));

    using (var conn = new ReliableSqlConnection(connStr, _policy))
    {
        // Do SQL stuff here.
    }
}
```

TFH also supports Azure In-Role Cache and Service Bus.

- When you use the Entity Framework you typically aren't working directly with SQL connections, so you can't use this Patterns and Practices package, but Entity Framework 6 builds this kind of retry logic right into the framework. In a similar way you specify the retry strategy, and then EF uses that strategy whenever it accesses the database.

  To use this feature in the Fix It app, all we have to do is add a class that derives from *DbConfiguration* and turn on the retry logic.

```
// EF follows a Code based Configuration model and will look for a class that
// derives from DbConfiguration for executing any Connection Resiliency strategies
public class EFConfiguration : DbConfiguration
{
    public EFConfiguration()
    {
        AddExecutionStrategy(() => new SqlAzureExecutionStrategy());
    }
}
```

  For SQL Database exceptions that the framework identifies as typically transient errors, the code shown instructs EF to retry the operation up to 3 times, with an exponential back-off delay between retries, and a maximum delay of 5 seconds. Exponential back-off means that after each failed retry it will wait for a longer period of time before trying again. If three tries in a row fail, it will throw an exception. The following section about circuit breakers explains why you want exponential back-off and a limited number of retries.

  You can have similar issues when you're using the Azure Storage service, as the Fix It app does for Blobs, and the .NET storage client API already implements the same kind of logic. You just specify the retry policy, or you don't even have to do that if you're happy with the default settings.

Circuit breakers

There are several reasons why you don't want to retry too many times over too long a period:

- Too many users persistently retrying failed requests might degrade other users' experience. If millions of people are all making repeated retry requests you could be tying up IIS dispatch queues and preventing your app from servicing requests that it otherwise could handle successfully.
- If everyone is retrying due to a service failure, there could be so many requests queued up that the service gets flooded when it starts to recover.
- If the error is due to throttling and there's a window of time the service uses for throttling, continued retries could move that window out and cause the throttling to continue.
- You might have a user waiting for a web page to render. Making people wait too long might be more annoying that relatively quickly advising them to try again later.

Exponential back-off addresses some of these issue by limiting the frequency of retries a service can get from your application. But you also need to have *circuit breakers*: this means that at a certain retry threshold your app stops retrying and takes some other action, such as one of the following:

- Custom fallback. If you can't get a stock price from Reuters, maybe you can get it from Bloomberg; or if you can't get data from the database, maybe you can get it from cache.
- Fail silent. If what you need from a service isn't all-or-nothing for your app, just return null when you can't get the data. If you're displaying a Fix It task and the Blob service isn't responding, you could display the task details without the image.
- Fail fast. Error out the user to avoid flooding the service with retry requests which could cause service disruption for other users or extend a throttling window. You can display a friendly "try again later" message.

There is no one-size-fits-all retry policy. You can retry more times and wait longer in an asynchronous background worker process than you would in a synchronous web app where a user is waiting for a response. You can wait longer between retries for a relational database service than you would for a cache service. Here are some sample recommended retry policies to give you an idea of how the numbers might vary. ("Fast First" means no delay before the first retry.

Platform	Context	Sample Target e2e latency max	Fast First	Retry Count	Delay	Backoff
Windows Azure Table Storage	Synchronous (e.g. render web page)	100 ms	Yes	3	25 ms	Linear
	Asynchronous (e.g. process queue item)	500 ms	Yes	3	100 ms	Exponential

For SQL Database retry policy guidance, see Troubleshoot transient faults and connection errors to SQL Database.

Summary

A retry/back-off strategy can help make temporary errors invisible to the customer most of the time, and Microsoft provides frameworks that you can use to minimize your work implementing a strategy whether you're using ADO.NET, Entity Framework, or the Azure Storage service.

In the next chapter, we'll look at how to improve performance and reliability by using distributed caching.

Distributed Caching (Building Real-World Cloud Apps with Azure)

2/20/2020 • 7 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

The previous chapter looked at transient fault handling and mentioned caching as a circuit breaker strategy. This chapter gives more background about caching, including when to use it, common patterns for using it, and how to implement it in Azure.

What is distributed caching

A cache provides high throughput, low-latency access to commonly accessed application data, by storing the data in memory. For a cloud app the most useful type of cache is distributed cache, which means the data is not stored on the individual web server's memory but on other cloud resources, and the cached data is made available to all of an application's web servers (or other cloud VMs that are used by the application).

When the application scales by adding or removing servers, or when servers are replaced due to upgrades or faults, the cached data remains accessible to every server that runs the application.

By avoiding the high latency data access of a persistent data store, caching can dramatically improve application responsiveness. For example, retrieving data from cache is much faster than retrieving it from a relational database.

A side benefit of caching is reduced traffic to the persistent data store, which may result in lower costs when there are data egress charges for the persistent data store.

When to use distributed caching

Caching works best for application workloads that do more reading than writing of data, and when the data

model supports the key/value organization that you use to store and retrieve data in cache. It's also more useful when application users share a lot of common data; for example, cache would not provide as many benefits if each user typically retrieves data unique to that user. An example where caching could be very beneficial is a product catalog, because the data does not change frequently, and all customers are looking at the same data.

The benefit of caching becomes increasingly measurable the more an application scales, as the throughput limits and latency delays of the persistent data store become more of a limit on overall application performance. However, you might implement caching for other reasons than performance as well. For data that doesn't have to be perfectly up-to-date when shown to the user, cache access can serve as a circuit breaker for when the persistent data store is unresponsive or unavailable.

Popular cache population strategies

In order to be able to retrieve data from cache, you have to store it there first. There are several strategies for getting data that you need into a cache:

- On Demand / Cache Aside

  The application tries to retrieve data from cache, and when the cache doesn't have the data (a "miss"), the application stores the data in the cache so that it will be available the next time. The next time the application tries to get the same data, it finds what it's looking for in the cache (a "hit"). To prevent fetching cached data that has changed on the database, you invalidate the cache when making changes to the data store.

- Background Data Push

  Background services push data into the cache on a regular schedule, and the app always pulls from the cache. This approach works great with high latency data sources that don't require you always return the latest data.

- Circuit Breaker

  The application normally communicates directly with the persistent data store, but when the persistent data store has availability problems, the application retrieves data from cache. Data may have been put in cache using either the cache aside or background data push strategy. This is a fault handling strategy rather than a performance enhancing strategy.

In order to keep data in the cache current, you can delete related cache entries when your application creates, updates, or deletes data. If it's alright for your application to sometimes get data that is slightly out-of-date, you can rely on a configurable expiration time to set a limit on how old cache data can be.

You can configure absolute expiration (amount of time since the cache item was created) or sliding expiration (amount of time since the last time a cache item was accessed). Absolute expiration is used when you are depending on the cache expiration mechanism to prevent the data from becoming too stale. In the Fix It app, we'll manually evict stale cache items and we'll use sliding expiration to keep the most current data in cache. Regardless of the expiration policy you choose, the cache will automatically evict the oldest (Least Recently Used or LRU) items when the cache's memory limit is reached.

Sample cache-aside code for Fix It app

In the following sample code, we check the cache first when retrieving a Fix It task. If the task is found in cache, we return it; if not found, we get it from the database and store it in the cache. The changes you'd make to add caching to the `FindTaskByIdAsync` method are highlighted.

```
public async Task<FixItTask> FindTaskByIdAsync(int id)
 {
    FixItTask fixItTask = null;
    Stopwatch timespan = Stopwatch.StartNew();
    string hitMiss = "Hit";

    try
    {
       fixItTask = (FixItTask)cache.Get(id.ToString());
       if (fixItTask == null)
       {
          fixItTask = await db.FixItTasks.FindAsync(id);
          cache.Put(id.ToString(), fixItTask);
          hitMiss = "Miss";
       }

       timespan.Stop();
       log.TraceApi("SQL Database", "FixItTaskRepository.FindTaskByIdAsync", timespan.Elapsed,
                    "cache {0}, id={1}", hitMiss, id);
    }
    catch (Exception e)
    {
       log.Error(e, "Error in FixItTaskRepository.FindTaskByIdAsynx(id={0})", id);
    }

    return fixItTask;
 }
```

When you update or delete a Fix It task, you have to invalidate (remove) the cached task. Otherwise, future attempts to read that task will continue to get the old data from the cache.

```
public async Task UpdateAsync(FixItTask taskToSave)
{
   Stopwatch timespan = Stopwatch.StartNew();

   try
   {
      cache.Remove(taskToSave.FixItTaskId.ToString());
      db.Entry(taskToSave).State = EntityState.Modified;
      await db.SaveChangesAsync();

      timespan.Stop();
      log.TraceApi("SQL Database", "FixItTaskRepository.UpdateAsync", timespan.Elapsed, "taskToSave={0}",
taskToSave);
   }
   catch (Exception e)
   {
      log.Error(e, "Error in FixItTaskRepository.UpdateAsync(taskToSave={0})", taskToSave);
   }
}
```

These are samples to illustrate simple caching code; caching has not been implemented in the downloadable Fix It project.

Azure caching services

Azure offers the following caching services: Azure Redis Cache and Azure Managed Cache. Azure Redis cache is based on the popular open source Redis Cache and is the first choice for most caching scenarios.

ASP.NET session state using a cache provider

As mentioned in the web development best practices chapter, a best practice is to avoid using session state. If

your application requires session state, the next best practice is to avoid the default in-memory provider because that doesn't enable scale out (multiple instances of the web server). The ASP.NET SQL Server session state provider enables a site that runs on multiple web servers to use session state, but it incurs a high latency cost compared to an in-memory provider. The best solution if you have to use session state is to use a cache provider, such as the Session State Provider for Azure Cache.

Summary

You've seen how the Fix It app could implement caching in order to improve response time and scalability, and to enable the app to continue to be responsive for read operations when the database is unavailable. In the next chapter we'll show how to further improve scalability and make the app continue to be responsive for write operations.

Resources

For more information about caching, see the following resources.

Documentation

- Azure Cache. Official MSDN documentation on caching in Azure.
- Microsoft Patterns and Practices - Azure Guidance. See Caching guidance and Cache-Aside pattern.
- Failsafe: Guidance for Resilient Cloud Architectures. White paper by Marc Mercuri, Ulrich Homann, and Andrew Townhill. See the section on Caching.
- Best Practices for the Design of Large-Scale Services on Azure Cloud Services. W. White paper by Mark Simms and Michael Thomassy. See the section on distributed caching.
- Distributed Caching On The Path To Scalability. An older (2009) MSDN Magazine article, but a clearly written introduction to distributed caching in general; goes into more depth than the caching sections of the FailSafe and Best Practices white papers.

Videos

- FailSafe: Building Scalable, Resilient Cloud Services. Nine-part series by Ulrich Homann, Marc Mercuri, and Mark Simms. Presents a 400-level view of how to architect cloud apps. This series focuses on theory and reasons why; for more how-to details, see the Building Big series by Mark Simms. See the caching discussion in episode 3 starting at 1:24:14.
- Building Big: Lessons learned from Azure customers - Part I. Simon Davies discusses distributed caching starting at 46:00. Similar to the Failsafe series but goes into more how-to details. The presentation was given October 31, 2012, so it does not cover caching service of Web Apps in Azure App Service that was introduced in 2013.

Code sample

- Cloud Service Fundamentals in Azure. Sample application that implements distributed caching. See the accompanying blog post Cloud Service Fundamentals – Caching Basics.

Queue-Centric Work Pattern (Building Real-World Cloud Apps with Azure)

2/20/2020 • 13 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

Earlier, we saw that using multiple services can result in a "composite" SLA, where the app's effective SLA is the *product* of the individual SLAs. For example, the Fix It app uses Web Sites, Storage, and SQL Database. If any one of these services fails, the app will return an error to the user.

Caching is a good way to handle transient failures for read-only content. But what if your application needs to do work? For example, when the user submits a new Fix It task, the app can't just put the task into the cache. The app needs to write the Fix It task into a persistent data store, so it can be processed.

That's where the queue-centric work pattern comes in. This pattern enables loose coupling between a web tier and a backend service.

Here's how the pattern works. When the application gets a request, it puts a work item onto a queue and immediately returns the response. Then a separate backend process pulls work items from the queue and does the work.

The queue-centric work pattern is useful for:

- Work that is time consuming (high latency).
- Work that requires an external service that might not always be available.
- Work that is resource-intensive (high CPU).
- Work that would benefit from rate leveling (subject to sudden load bursts).

Reduced Latency

Queues are useful any time you are doing time-consuming work. If a task takes a few seconds or longer, instead of blocking the end user, put the work item into a queue. Tell the user "We're working on it," and then use a queue listener to process the task in the background.

For example, when you purchase something at an online retailer, the web site confirms your order immediately. But that doesn't mean your stuff is already in a truck being delivered. They put a task in a queue, and in the background they are doing the credit check, preparing your items for shipping, and so forth.

For scenarios with short latency, the total end-to-end time might be longer using a queue, compared with doing the task synchronously. But even then, the other benefits can outweigh that disadvantage.

Increased Reliability

In the version of Fix It that we've been looking at so far, the web front-end is tightly coupled with the SQL Database back-end. If the SQL database service is unavailable, the user gets an error. If retries don't work (that is,

the failure is more than transient), the only thing you can do is show an error and ask the user to try again later.

Using queues, when a user submits a Fix It task, the app writes a message to the queue. The message payload is a JSON representation of the task. As soon as the message is written to the queue, the app returns and immediately shows a success message to the user.

If any of the backend services – such as the SQL database or the queue listener -- go offline, users can still submit new Fix It tasks. The messages will just queue up until the backend services are available again. At that point, the backend services will catch up on the backlog.

Moreover, now you can add more backend logic without worrying about the resiliency of the front end. For example, you might want to send an email or SMS message to the owner whenever a new Fix It is assigned. If the email or SMS service becomes unavailable, you can process everything else, and then put a message into a separate queue for sending email/SMS messages.

Previously, our effective SLA was Web Apps × Storage × SQL Database = 99.7%. (See Design to Survive Failures.)

When we change the app to use a queue, the web front end depends only on Web Apps and Storage, for a composite SLA of 99.8%. (Note that queues are part of the Azure storage service, so they are included in the same SLA as blob storage.)

If you need even better than 99.8%, you can create two queues in two different regions. Designate one as the primary, and the other as the secondary. In your app, fail over to the secondary queue if the primary queue is not available. The chance of both being unavailable at the same time is very small.

Rate Leveling and Independent Scaling

Queues are also useful for something called *rate leveling* or *load leveling*.

Web apps are often susceptible to sudden bursts in traffic. While you can use autoscaling to automatically add web servers to handle increased web traffic, autoscaling might not be able to react quickly enough to handle abrupt spikes in load. If the web servers can offload some of the work they have to do by writing a message to a queue, they can handle more traffic. A backend service can then read messages from the queue and process them. The depth of the queue will grow or shrink as the incoming load varies.

With much of its time-consuming work off-loaded to a backend service, the web tier can more easily respond to sudden spikes in traffic. And you save money because any given amount of traffic can be handled by fewer web

servers.

You can scale the web tier and backend service independently. For example, you might need three web servers but only one server processing queue messages. Or if you're running a compute-intensive task in the background, you might need more backend servers.

Autoscaling works with backend services as well as with the web tier. You can scale up or scale down the number of VMs that are processing the tasks in the queue, based on the CPU usage of the backend VMs. Or, you can autoscale based on how many items are in a queue. For example, you can tell autoscale to try to keep no more than 10 items in the queue. If the queue has more than 10 items, autoscale will add VMs. When they catch up, autoscale will tear down the extra VMs.

Adding Queues to the Fix It Application

To implement the queue pattern, we need to make two changes to the Fix It app.

- When a user submits a new Fix It task, put the task in the queue, instead of writing it to the database.
- Create a back-end service that processes messages in the queue.

For the queue, we'll use the Azure Queue Storage Service. Another option is to use Azure Service Bus.

To decide which queue service to use, consider how your app needs to send and receive the messages in the queue:

- If you have cooperating producers and competing consumers, consider using Azure Queue Storage Service. "Cooperating producers" means multiple processes are adding messages to a queue. "Competing consumers" means multiple processes are pulling messages off the queue to process them, but any given message can only be processed by one "consumer." If you need more throughput than you can get with a single queue, use additional queues and/or additional storage accounts.
- If you need a publish/subscribe model, consider using Azure Service Bus Queues.

The Fix It app fits the cooperating producers and competing consumers model.

Another consideration is application availability. The Queue Storage Service is part of the same service that we're using for blob storage, so using it has no effect on our SLA. Azure Service Bus is a separate service with its own SLA. If we used Service Bus Queues, we would have to factor in an additional SLA percentage, and our composite SLA would be lower. When you're choosing a queue service, make sure you understand the impact of your choice on application availability. For more information, see the Resources section.

Creating Queue Messages

To put a Fix It task on the queue, the web front end performs the following steps:

1. Create a CloudQueueClient instance. The `CloudQueueClient` instance is used to execute requests against the Queue Service.
2. Create the queue, if it doesn't exist yet.
3. Serialize the Fix It task.
4. Call CloudQueue.AddMessageAsync to put the message onto the queue.

We'll do this work in the constructor and `SendMessageAsync` method of a new `FixItQueueManager` class.

```
public class FixItQueueManager : IFixItQueueManager
{
    private CloudQueueClient _queueClient;
    private IFixItTaskRepository _repository;

    private static readonly string fixitQueueName = "fixits";

    public FixItQueueManager(IFixItTaskRepository repository)
    {
        _repository = repository;
        CloudStorageAccount storageAccount = StorageUtils.StorageAccount;
        _queueClient = storageAccount.CreateCloudQueueClient();
    }

    // Puts a serialized fixit onto the queue.
    public async Task SendMessageAsync(FixItTask fixIt)
    {
        CloudQueue queue = _queueClient.GetQueueReference(fixitQueueName);
        await queue.CreateIfNotExistsAsync();

        var fixitJson = JsonConvert.SerializeObject(fixIt);
        CloudQueueMessage message = new CloudQueueMessage(fixitJson);

        await queue.AddMessageAsync(message);
    }

    // Processes any messages on the queue.
    public async Task ProcessMessagesAsync()
    {
        CloudQueue queue = _queueClient.GetQueueReference(fixitQueueName);
        await queue.CreateIfNotExistsAsync();

        while (true)
        {
            CloudQueueMessage message = await queue.GetMessageAsync();
            if (message == null)
            {
                break;
            }
            FixItTask fixit = JsonConvert.DeserializeObject<FixItTask>(message.AsString);
            await _repository.CreateAsync(fixit);
            await queue.DeleteMessageAsync(message);
        }
    }
}
```

Here we are using the Json.NET library to serialize the fixit to JSON format. You can use whatever serialization approach you prefer. JSON has the advantage of being human-readable, while being less verbose than XML.

Production-quality code would add error handling logic, pause if the database became unavailable, handle recovery more cleanly, create the queue on application start-up, and manage "poison" messages. (A poison message is a message that cannot be processed for some reason. You don't want poison messages to sit in the queue, where the worker role will continually try to process them, fail, try again, fail, and so on.)

In the front-end MVC application, we need to update the code that creates a new task. Instead of putting the task

into the repository, call the `SendMessageAsync` method shown above.

```
public async Task<ActionResult> Create(FixItTask fixittask, HttpPostedFileBase photo)
{
    if (ModelState.IsValid)
    {
        fixittask.CreatedBy = User.Identity.Name;
        fixittask.PhotoUrl = await photoService.UploadPhotoAsync(photo);
        //previous code:
        //await fixItRepository.CreateAsync(fixittask);
        //new code:
        await queueManager.SendMessageAsync(fixittask);
        return RedirectToAction("Success");
    }
    return View(fixittask);
}
```

Processing Queue Messages

To process messages in the queue, we'll create a backend service. The backend service will run an infinite loop that performs the following steps:

1. Get the next message from the queue.
2. Deserialize the message to a Fix It task.
3. Write the Fix It task to the database.

To host the backend service, we'll create an Azure Cloud Service that contains a *worker role*. A worker role consists of one or more VMs that can do backend processing. The code that runs in these VMs will pull messages from the queue as they become available. For each message, we'll deserialize the JSON payload and write an instance of the Fix It Task entity to the database, using the same repository that we used earlier in the web tier.

The following steps show how to add a worker role project to a solution that has a standard web project. These steps have already been done in the Fix It project that you can download.

First add a Cloud Service project to the Visual Studio solution. Right-click the solution and select **Add**, then **New Project**. In the left pane, expand **Visual C#** and select **Cloud**.

In the **New Azure Cloud Service** dialog, expand the **Visual C#** node on the left pane. Select **Worker Role** and click the right-arrow icon.

(Notice that you can also add a *web role*. We could run the Fix It front-end in the same Cloud Service instead of running it in an Azure Web Site. That has some advantages in making connections between front-end and back-end easier to coordinate. However, to keep this demo simple, we're keeping the front-end in an Azure App Service Web App and only running the back-end in a Cloud Service.)

A default name is assigned to the worker role. To change the name, hover the mouse over the worker role in the right pane, then click the pencil icon.

Click **OK** to complete the dialog. This adds two projects to the Visual Studio solution.

- an Azure project that defines the cloud service, including configuration information.
- A worker role project that defines the worker role.

For more information, see Creating an Azure Project with Visual Studio.

Inside the worker role, we poll for messages by calling the `ProcessMessageAsync` method of the `FixItQueueManager` class that we saw earlier.

```
public class WorkerRole : RoleEntryPoint
{
    public override void Run()
    {
        Task task = RunAsync(tokenSource.Token);
        try
        {
            task.Wait();
        }
        catch (Exception ex)
        {
            logger.Error(ex, "Unhandled exception in FixIt worker role.");
        }
    }

    private async Task RunAsync(CancellationToken token)
    {
        using (var scope = container.BeginLifetimeScope())
        {
            IFixItQueueManager queueManager = scope.Resolve<IFixItQueueManager>();
            while (!token.IsCancellationRequested)
            {
                try
                {
                    await queueManager.ProcessMessagesAsync();
                }
                catch (Exception ex)
                {
                    logger.Error(ex, "Exception in worker role Run loop.");
                }
                await Task.Delay(1000);
            }
        }
    }
    // Other code not shown.
}
```

The `ProcessMessagesAsync` method checks if there's a message waiting. If there is one, it deserializes the message into a `FixItTask` entity and saves the entity in the database. It loops until the queue is empty.

```
public async Task ProcessMessagesAsync()
{
    CloudQueue queue = _queueClient.GetQueueReference(fixitQueueName);
    await queue.CreateIfNotExistsAsync();
    while (true)
    {
        CloudQueueMessage message = await queue.GetMessageAsync();
        if (message == null)
        {
            break;
        }
        FixItTask fixit = JsonConvert.DeserializeObject<FixItTask>(message.AsString);
        await _repository.CreateAsync(fixit);
        await queue.DeleteMessageAsync(message);
    }
}
```

Polling for queue messages incurs a small transaction charge, so when there's no message waiting to be processed, the worker role's `RunAsync` method waits a second before polling again by calling `Task.Delay(1000)`.

In a web project, adding asynchronous code can automatically improve performance because IIS manages a limited thread pool. That is not the case in a worker role project. To improve scalability of the worker role, you can write multi-threaded code or use asynchronous code to implement parallel programming. The sample doesn't implement parallel programming but shows how to make the code asynchronous so you can implement parallel programming.

Summary

In this chapter you've seen how to improve application responsiveness, reliability, and scalability by implementing the queue-centric work pattern.

This is the last of the 13 patterns covered in this e-book, but there are of course many other patterns and practices that can help you build successful cloud apps. The final chapter provides links to resources for topics that haven't been covered in these 13 patterns.

Resources

For more information about queues, see the following resources.

Documentation:

- Microsoft Azure Storage Queues Part 1: Getting Started. Article by Roman Schacherl.
- Executing Background Tasks, chapter 5 of Moving Applications to the Cloud, 3rd Edition from Microsoft Patterns and Practices. (In particular, the section "Using Azure Storage Queues".)
- Best Practices for Maximizing Scalability and Cost Effectiveness of Queue-Based Messaging Solutions on Azure. White paper by Valery Mizonov.
- Comparing Azure Queues and Service Bus Queues. MSDN Magazine article, provides additional information that can help you choose which queue service to use. The article mentions that Service Bus is dependent on ACS for authentication, which means your SB queues would be unavailable when ACS is unavailable. However, since the article was written, SB was changed to enable you to use SAS tokens as an alternative to ACS.
- Microsoft Patterns and Practices - Azure Guidance. See Asynchronous Messaging primer, Pipes and Filters pattern, Compensating Transaction pattern, Competing Consumers pattern, CQRS pattern.
- CQRS Journey. E-book about CQRS by Microsoft Patterns and Practices.

Video:

- FailSafe: Building Scalable, Resilient Cloud Services. Nine-part video series by Ulrich Homann, Marc Mercuri,

and Mark Simms. Presents high-level concepts and architectural principles in a very accessible and interesting way, with stories drawn from Microsoft Customer Advisory Team (CAT) experience with actual customers. For an introduction to the Azure Storage service and queues, see episode 5 starting at 35:13.

More Patterns and Guidance (Building Real-World Cloud Apps with Azure)

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson, Rick Anderson, Tom Dykstra

Download Fix It Project or Download E-book

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

You've now seen 13 patterns that provide guidance on how to be successful in cloud computing. These are just a few of the patterns that apply to cloud apps. Here are some more cloud computing topics, and resources to help with them:

- Migrating existing on-premises applications to the cloud.
  - Moving Applications to the Cloud. E-book by Microsoft Patterns and Practices. Also available as a hard-copy paperback.
  - Migrating Microsoft's ASP.NET and IIS.NET. Case study by Robert McMurray.
  - Moving 4th & Mayor to Azure Web Sites. Blog post by Jeff Wilcox chronicling his experience moving a web app from Amazon Web Services to Web Apps in Azure App Service.
  - Moving Apps to Azure: What changes? Short video by Stefan Schackow, explains file system access in Web Apps in Azure App Service.
  - Azure Hybrid Cloud. Hardcopy book or e-book by Danny Garber, Jamal Malik, and Adam Fazio.
- Security, authentication, and authorization issues unique to cloud applications
  - Azure Security Guidance
  - Microsoft Patterns and Practices - Azure Guidance. See Gatekeeper pattern, Federated Identity pattern.
  - Azure Network Security. White paper by Ashin Palekar.

See also additional cloud computing patterns and guidance at Microsoft Patterns and Practices - Azure Guidance.

Resources

Each of the chapters in this e-book provides links to resources for more information about that specific topic. The following list provides links to overviews of best practices and recommended patterns for successful cloud development with Azure.

Documentation

- Best Practices for the Design of Large-Scale Services on Azure Cloud Services. White paper by Mark Simms and Michael Thomassy.
- Failsafe: Guidance for Resilient Cloud Architectures. White paper by Marc Mercuri, Ulrich Homann, and Andrew Townhill. Web page version of the FailSafe video series.
- Azure Guidance Portal page for official documentation related to developing applications for Azure.

Videos

- Building Real World Cloud Apps with Azure - Part 1 and Part 2. Video of the presentation by Scott Guthrie that this e-book is based on. Presented at Tech Ed Australia in September, 2013. An earlier version of the same presentation was delivered at Norwegian Developers Conference (NDC) in June, 2013: NDC part 1, NDC part 2.
- FailSafe: Building Scalable, Resilient Cloud Services. Nine-part video series by Ulrich Homann, Marc Mercuri, and Mark Simms. Presents a 400-level view of how to architect cloud apps. This series focuses on theory and reasons behind recommended patterns; for more how-to details, see the Building Big series by Mark Simms.
- Building Big: Lessons learned from Azure customers- Part 1 and Part 2. Two-part video series by Simon Davies and Mark Simms, similar to the FailSafe series but oriented more toward practical implementation.

Code sample

- The Fix It application that accompanies this e-book.
- Cloud Service Fundamentals in Azure in C# for Visual Studio 2012. Downloadable project in the Microsoft Code Gallery site, includes both code and documentation developed by the Microsoft Customer Advisory Team (CAT). Demonstrates many of the best practices advocated in the FailSafe and Building Big video series and the FailSafe white paper. The Code Gallery page also links to extensive documentation by the authors of the project -- see especially the Cloud Service Fundamentals wiki collection link in the blue box near the top of the project description. This project and the documentation for it still actively being developed, making it a better choice for information on many topics than similar but older white papers.

Hard copy books

- Cloud Computing Bible. By Barrie Sosinsky.
- Release It! Design and Deploy Production-Ready Software. By Michael T. Nygard.
- Cloud Architecture Patterns: Using Microsoft Azure. By Bill Wilder.
- Windows Azure Platform. By Tejaswi Redkar.
- Windows Azure programming patterns for Start-ups. By Riccardo Becker.
- Microsoft Windows Azure Development Cookbook. By Neil Mackenzie.

Finally, when you get started building real-world apps and running them in Azure, sooner or later you'll probably need assistance from experts. You can ask questions in community sites such as Azure forums or StackOverflow, or you can contact Microsoft directly for Azure support. Microsoft offers several levels of technical support Azure: for a summary and comparison of the options, see Azure Support.

Acknowledgments

This content was written by Tom Dykstra, Rick Anderson, and Mike Wasson. Most of the original content came from Scott Guthrie, and he in turn drew on material from Mark Simms and the Microsoft Customer Advisory Team (CAT).

Many other colleagues at Microsoft reviewed and commented on drafts and code:

- Tim Ammann - Reviewed the automation chapter.
- Christopher Bennage - Reviewed and tested the Fix It code.
- Ryan Berry - Reviewed the CD/CI chapter.
- Vittorio Bertocci - Reviewed the SSO chapter.
- Chris Clayton - Helped resolve technical problems in the PowerShell scripts.
- Conor Cunningham - Reviewed the data storage options chapter.
- Carlos Farre - Reviewed and tested the Fix It code for security issues.
- Larry Franks - Reviewed the telemetry and monitoring chapter.
- Jonathan Gao - Reviewed Hadoop and MapReduce sections of the data storage options chapter.
- Sidney Higa - Reviewed all chapters.

- Gordon Hogenson - Reviewed the source control chapter.
- Tamra Myers - Reviewed data storage options, blob, and queues chapters.
- Pranav Rastogi - Reviewed the SSO chapter.
- June Blender Rogers - Added error handling and help to the PowerShell automation scripts.
- Mani Subramanian - Reviewed all chapters and led the code review and testing process for the Fix It code.
- Shaun Tinline-Jones - Reviewed the data partitioning chapter.
- Selcin Tukarslan - Reviewed chapters that cover SQL Database and SQL Server.
- Edward Wu - Provided sample code for the SSO chapter.
- Guang Yang - Wrote the PowerShell automation scripts.

Members of the Microsoft Developer Guidance Advisory Council (DGAC) also reviewed and commented on drafts:

- Jean-Luc Boucho
- Catalin Gheorghiu
- Wouter de Kort
- Carlos dos Santos
- Neil Mackenzie
- Dennis Persson
- Sunil Sabat
- Aleksey Sinyagin
- Bill Wagner
- Michael Wood

Other members of the DGAC reviewed and commented on the preliminary outline:

- Damir Arh
- Edward Bakker
- Srdjan Bozovic
- Ming Man Chan
- Gianni Rosa Gallina
- Paulo Morgado
- Jason Oliveira
- Alberto Poblacion
- Ryan Riley
- Perez Jones Tsisah
- Roger Whitehead
- Pawel Wilkosz

Appendix: The Fix It Sample Application (Building Real-World Cloud Apps with Azure)

by Mike Wasson, Rick Anderson, Tom Dykstra

Download The Fix It Project

> The **Building Real World Cloud Apps with Azure** e-book is based on a presentation developed by Scott Guthrie. It explains 13 patterns and practices that can help you be successful developing web apps for the cloud. For information about the e-book, see the first chapter.

This appendix to the Building Real World Cloud Apps with Azure e-book contains the following sections that provide additional information about the Fix It sample application that you can download:

- Known issues
- Best practices
- How to run the app from Visual Studio on your local computer
- How to deploy the base app to Azure App Service Web Apps by using the Windows PowerShell scripts
- Troubleshooting the Windows PowerShell scripts
- How to deploy the app with queue processing to Azure App Service Web Apps and an Azure Cloud Service

Known issues

The Fix It app was originally developed in order to illustrate as simply as possible some of the patterns presented in this e-book. However, since the e-book is about building real-world apps, we subjected the Fix It code to a review and testing process similar to what we'd do for released software. We found a number of issues, and as with any real-world application, some of them we fixed and some of them we deferred to a later release.

The following list includes issues that should be addressed in a production application, but for one reason or another we decided not to address in the initial release of the Fix It sample application.

Security

- Ensure that you can't assign a task to a non-existent owner.
- Ensure that you can only view and modify tasks that you created or are assigned to you.
- Use HTTPS for sign-in pages and authentication cookies.
- Specify a time limit for authentication cookies.

Input validation

In general, a production app would do more input validation than the Fix It app. For example, the image size / image file size allowed for upload should be limited.

Administrator functionality

An administrator should be able to change ownership on existing tasks. For example, the creator of a task might leave the company, leaving no one with authority to maintain the task unless administrative access is enabled.

Queue message processing

Queue message processing in the Fix It app was designed to be simple in order to illustrate the queue-centric work pattern with a minimum amount of code. This simple code would not be adequate for an actual production

application.

- The code does not guarantee that each queue message will be processed at most once. When you get a message from the queue, there is a timeout period, during which the message is invisible to other queue listeners. If the timeout expires before the message is deleted, the message becomes visible again. Therefore, if a worker role instance spends a long time processing a message, it is theoretically possible for the same message to get processed twice, resulting in a duplicate task in the database. For more information about this issue, see Using Azure Storage Queues.
- The queue polling logic could be more cost-effective, by batching message retrieval. Every time you call CloudQueue.GetMessageAsync, there is a transaction cost. Instead, you can call CloudQueue.GetMessagesAsync (note the plural 's'), which gets multiple messages in a single transaction. The transaction costs for Azure Storage Queues are very low, so the impact on costs is not substantial in most scenarios.
- The tight loop in the queue message-processing code causes CPU affinity, which does not utilize multi-core VMs efficiently. A better design would use task parallelism to run several async tasks in parallel.
- Queue message-processing has only rudimentary exception handling. For example, the code doesn't handle poison messages. (When message processing causes an exception, you have to log the error and delete the message, or the worker role will try to process it again, and the loop will continue indefinitely.)

SQL queries are unbounded

Current Fix It code places no limit on how many rows the queries for Index pages might return. If a large volume of tasks is entered into the database, the size of the resulting lists received could cause performance issues. The solution is to implement paging. For an example, see Sorting, Filtering, and Paging with the Entity Framework in an ASP.NET MVC Application.

View models recommended

The Fix It app uses the FixItTask entity class to pass information between the controller and the view. A best practice is to use view models. The domain model (e.g., the FixItTask entity class) is designed around what is needed for data persistence, while a view model can be designed for data presentation. For more information, see 12 ASP.NET MVC Best Practices.

Secure image blob recommended

The Fix It app stores uploaded images as public, meaning that anyone who finds the URL can access the images. The images could be secured instead of public.

No PowerShell automation scripts for queues

Sample PowerShell automation scripts were written only for the base version of Fix It that runs entirely in Azure App Service Web Apps. We haven't provided scripts for setting up and deploying to the web app plus Cloud Service environment required for queue processing.

Special handling for HTML codes in user input

ASP.NET automatically prevents many ways in which malicious users might attempt cross-site scripting attacks by entering script in user input text boxes. And the MVC `DisplayFor` helper used to display task titles and notes automatically HTML-encodes values that it sends to the browser. But in a production app you might want to take additional measures. For more information, see Request Validation in ASP.NET.

Best practices

Following are some issues that were fixed after being discovered in code review and testing of the original version of the Fix It app. Some were caused by the original coder not being aware of a particular best practice, some simply because the code was written quickly and wasn't intended for released software. We're listing the issues here in case there's something we learned from this review and testing that might be helpful to others who are also developing web apps.

Dispose the database repository

The `FixItTaskRepository` class must dispose the Entity Framework `DbContext` instance. We did this by implementing `IDisposable` in the `FixItTaskRepository` class:

```
public class FixItTaskRepository : IFixItTaskRepository, IDisposable
{
    private MyFixItContext db = new MyFixItContext();

    // other code not shown

    public void Dispose()
    {
        Dispose(true);
        GC.SuppressFinalize(this);
    }

    protected virtual void Dispose(bool disposing)
    {
        if (disposing)
        {
            // Free managed resources.
            if (db != null)
            {
                db.Dispose();
                db = null;
            }
        }
    }
}
```

Note that AutoFac will automatically dispose the `FixItTaskRepository` instance, so we don't need to explicitly dispose it.

Another option is to remove the `DbContext` member variable from `FixItTaskRepository`, and instead create a local `DbContext` variable within each repository method, inside a `using` statement. For example:

```
// Alternate way to dispose the DbContext
using (var db = new MyFixItContext())
{
    fixItTask = await db.FixItTasks.FindAsync(id);
}
```

Register singletons as such with DI

Since only one instance of the `PhotoService` class and `Logger` class is needed, these classes should be registered as single instances for dependency injection in *DependenciesConfig.cs*:

```
builder.RegisterType<Logger>().As<ILogger>().SingleInstance();
builder.RegisterType<FixItTaskRepository>().As<IFixItTaskRepository>();
builder.RegisterType<PhotoService>().As<IPhotoService>().SingleInstance();
```

Security: Don't show error details to users

The original Fix It app didn't have a generic error page and just let all exceptions bubble up to the UI, so some exceptions such as database connection errors could result in a full stack trace being displayed to the browser. Detailed error information can sometimes facilitate attacks by malicious users. The solution is to log the exception details and display an error page to the user that doesn't include error details. The Fix It app was already logging, and in order to display an error page, we added `<customErrors mode=On>` in the Web.config file.

```
<system.web>
  <customErrors mode="On"/>
  <authentication mode="None" />
  <compilation debug="true" targetFramework="4.5" />
  <httpRuntime targetFramework="4.5" />
</system.web>
```

By default this causes *Views\Shared\Error.cshtml* to be displayed for errors. You can customize *Error.cshtml* or create your own error page view and add a `defaultRedirect` attribute. You can also specify different error pages for specific errors.

Security: only allow a task to be edited by its creator

The Dashboard Index page only shows tasks created by the logged-on user, but a malicious user could create a URL with an ID to another user's task. We added code in *DashboardController.cs* to return a 404 in that case:

```
public async Task<ActionResult> Edit(int id)
{
    FixItTask fixittask = await fixItRepository.FindTaskByIdAsync(id);
    if (fixittask == null)
    {
        return HttpNotFound();
    }

    // Verify logged in user owns this FixIt task.
    if (User.Identity.Name != fixittask.Owner)
    {
       return HttpNotFound();
    }

    return View(fixittask);
}

[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Edit(int id, [Bind(Include =
"CreatedBy,Owner,Title,Notes,PhotoUrl,IsDone")]FormCollection form)
{
    FixItTask fixittask = await fixItRepository.FindTaskByIdAsync(id);

    // Verify logged in user owns this FixIt task.
    if (User.Identity.Name != fixittask.Owner)
    {
       return HttpNotFound();
    }

    if (TryUpdateModel(fixittask, form))
    {
        await fixItRepository.UpdateAsync(fixittask);
        return RedirectToAction("Index");
    }

    return View(fixittask);
}
```

Don't swallow exceptions

The original Fix It app just returned null after logging an exception that resulted from a SQL query:

```
catch (Exception e)
{
    log.Error(e, "Error in FixItTaskRepository.FindTasksByOwnerAsync(userName={0})", userName);
    return null;
}
```

This would make it look to the user as if the query succeeded but just didn't return any rows. Solution is to re-throw the exception after catching and logging:

```
catch (Exception e)
{
    log.Error(e, "Error in FixItTaskRepository.FindTasksByCreatorAsync(creater={0})", creator);
    throw;
}
```

Catch all exceptions in worker roles

Any unhandled exceptions in a worker role will cause the VM to be recycled, so you want to wrap everything you do in a try-catch block and handle all exceptions.

Specify length for string properties in entity classes

In order to display simple code, the original version of the Fix It app didn't specify lengths for the fields of the FixItTask entity, and as a result they were defined as varchar(max) in the database. As a result, the UI would accept almost any amount of input. Specifying lengths sets limits that apply both to user input in the web page and column size in the database:

```
public class FixItTask
{
    public int FixItTaskId  { get; set; }
    [StringLength(80)]
    public string CreatedBy { get; set; }
    [Required]
    [StringLength(80)]
    public string Owner { get; set; }
    [Required]
    [StringLength(80)]
    public string Title { get; set; }
    [StringLength(1000)]
    public string Notes { get; set; }
    [StringLength(200)]
    public string PhotoUrl { get; set; }
    public bool IsDone      { get; set; }
}
```

Mark private members as readonly when they aren't expected to change

For example, in the `DashboardController` class an instance of `FixItTaskRepository` is created and isn't expected to change, so we defined it as readonly.

```
public class DashboardController : Controller
    {
        private readonly IFixItTaskRepository fixItRepository = null;
```

Use list.Any() instead of list.Count() > 0

If you all you care about is whether one or more items in a list fit the specified criteria, use the Any method, because it returns as soon as an item fitting the criteria is found, whereas the `Count` method always has to iterate through every item. The Dashboard *Index.cshtml* file originally had this code:

```
@if (Model.Count() == 0) {
    <br />
    <div>You don't have anything currently assigned to you!!!</div>
}
```

We changed it to this:

```
@if (!Model.Any()) {
    <br />
    <div>You don't have anything currently assigned to you!!!</div>
}
```

Generate URLs in MVC views using MVC helpers

For the **Create a Fix It** button on the home page, the Fix It app hard coded an anchor element:

```
<a href="/Tasks/Create" class="btn btn-primary btn-large">Create a New FixIt &raquo;</a>
```

For View/Action links like this it's better to use the Url.Action HTML helper, for example:

```
@Url.Action("Create","Tasks")
```

Use Task.Delay instead of Thread.Sleep in worker role

The new-project template puts `Thread.Sleep` in the sample code for a worker role, but causing the thread to sleep can cause the thread pool to spawn additional unnecessary threads. You can avoid that by using Task.Delay instead.

```
while (true)
{
    try
    {
        await queueManager.ProcessMessagesAsync();
    }
    catch (Exception ex)
    {
        logger.Error(ex, "Exception in worker role Run loop.");
    }
    await Task.Delay(1000);
}
```

Avoid async void

If an async method doesn't need to return a value, return a `Task` type rather than `void`.

This example is from the `FixItQueueManager` class:

```
// Correct
public async Task SendMessageAsync(FixItTask fixIt) { ... }

// Incorrect
public async void SendMessageAsync(FixItTask fixIt) { ... }
```

You should use `async void` only for top-level event handlers. If you define a method as `async void`, the caller cannot **await** the method or catch any exceptions the method throws. For more information, see Best Practices in Asynchronous Programming.

Use a cancellation token to break from worker role loop

Typically, the **Run** method on a worker role contains an infinite loop. When the worker role is stopping, the RoleEntryPoint.OnStop method is called. You should use this method to cancel the work that is being done inside the **Run** method and exit gracefully. Otherwise, the process might be terminated in the middle of an operation.

Opt out of Automatic MIME Sniffing Procedure

In some cases, Internet Explorer reports a MIME type different than the type specified by the web server. For instance, if Internet Explorer finds HTML content in a file delivered with the HTTP response header Content-Type: text/plain, Internet Explorer determines that the content should be rendered as HTML. Unfortunately, this "MIME-sniffing" can also lead to security problems for servers hosting untrusted content. To combat this problem, Internet Explorer 8 has made a number of changes to MIME-type determination code and allows application developers to opt out of MIME-sniffing. The following code was added to the *Web.config* file.

```
<system.webServer>
     <httpProtocol>
        <customHeaders>
           <add name="X-Content-Type-Options" value="nosniff"/>
        </customHeaders>
     </httpProtocol>
     <modules>
      <remove name="FormsAuthenticationModule" />
    </modules>
  </system.webServer>
```

Enable bundling and minification

When Visual Studio creates a new web project, bundling and minification of JavaScript files is not enabled by default. We added a line of code in BundleConfig.cs:

```
// For more information on bundling, visit https://go.microsoft.com/fwlink/?LinkId=301862
public static void RegisterBundles(BundleCollection bundles)
{
    bundles.Add(new ScriptBundle("~/bundles/jquery").Include(
                "~/Scripts/jquery-{version}.js"));

   // Code removed for brevity/

   BundleTable.EnableOptimizations = true;
}
```

Set an expiration time-out for authentication cookies

By default, authentication cookies expire in two weeks. A shorter time is more secure. You can change this setting in *StartupAuth.cs*:

```
app.UseCookieAuthentication(new CookieAuthenticationOptions
{
    AuthenticationType = DefaultAuthenticationTypes.ApplicationCookie,
    LoginPath = new PathString("/Account/Login"),
    ExpireTimeSpan = System.TimeSpan.FromMinutes(20)
});
```

How to run the app from Visual Studio on your local computer

There are two ways to run the Fix It app:

- Run the base application that writes new tasks directly to the SQL database.
- Run the application using a queue plus a backend service to create tasks. The queue pattern is described in the

chapter Queue-Centric Work Pattern.

Run the base application

1. Install Visual Studio 2017.
2. Install the Azure SDK for .NET for Visual Studio.
3. Download the .zip file from the MSDN Code Gallery.
4. In File Explorer, right-click the .zip file and click Properties, then in the Properties window click Unblock.
5. Unzip the file.
6. Double-click the .sln file to launch Visual Studio.
7. From the **Tools** menu, click **NuGet Package Manager**, then **Package Manager Console**.
8. In the Package Manager Console (PMC), click Restore.
9. Exit Visual Studio.
10. Start the Azure Storage Emulator.
11. Restart Visual Studio, opening the solution file you closed in the previous step.
12. Make sure the FixIt project is set as the startup project, and then press CTRL+F5 to run the project.

Run the application with queue processing

1. Follow the directions for Run the base application, and then close the browser and close Visual Studio.
2. Start Visual Studio with administrator privileges. (You'll be using the Azure compute emulator, and that requires administrator privileges.)
3. In the application *Web.config* file in the *MyFixIt* project (the web project), change the value of `appSettings/UseQueues` to "true":

   ```
   <appSettings>
       <!-- Other settings not shown -->
       <add key="UseQueues" value="true"/>
   </appSettings>
   ```

4. If the Azure Storage Emulator isn't still running, start it again.
5. Run the FixIt web project and the MyFixItCloudService project simultaneously.

   Using Visual Studio:

   a. Press **F5** to run the FixIt project.
   b. In **Solution Explorer**, right-click the MyFixItCloudService project, and then click **Debug** > **Start New Instance**.

   Using Visual Studio 2013 Express for Web:

   c. In Solution Explorer, right-click the FixIt solution and select **Properties**.
   d. Select **Multiple Startup Projects**.
   e. In the **Action** dropdown list under MyFixIt and MyFixItCloudService, select **Start**.
   f. Click **OK**.
   g. Press **F5** to run both projects.

      When you run the MyFixItCloudService project, Visual Studio starts the Azure compute emulator. Depending on your firewall configuration, you might need to allow the emulator through the firewall.

How to deploy the base app to Azure App Service Web Apps by using the Windows PowerShell scripts

To illustrate the Automate Everything pattern, the Fix It app is supplied with scripts that set up an environment in Azure and deploy the project to the new environment. The following instructions explain how to use the scripts.

If you want to run in Azure without using queues, and you made the changes to run locally with queues, make sure you set the UseQueues appSetting value back to false before proceeding with the following instructions.

These instructions assume you have already downloaded and run the Fix It solution locally, and that you have an Azure account or have an Azure subscription that you are authorized to manage.

1. Install the **Azure PowerShell** console. For instructions, see How to install and configure Azure PowerShell.

   This customized console is configured to work with your Azure subscription. The Azure module is installed in the *Program Files* directory and is automatically imported on every use of the Azure PowerShell console.

   If you prefer to work in a different host program, such as Windows PowerShell ISE, be sure to use the Import-Module cmdlet to import the Azure module or use a command in the Azure module to trigger automatic importing of the module.

2. Start Azure PowerShell with the **Run as administrator** option.

3. Run the Set-ExecutionPolicy cmdlet to set the Azure PowerShell execution policy to `RemoteSigned`. Enter **Y** (for Yes) to complete the policy change.

   ```
   PS C:\> Set-ExecutionPolicy RemoteSigned
   ```

   This setting enables you to run local scripts that aren't digitally signed. (You can also set the execution policy to `Unrestricted`, which would eliminate the need for the unblock step later, but this is not recommended for security reasons.)

4. Run the `Add-AzureAccount` cmdlet to set up PowerShell with credentials for your account.

   ```
   PS C:\> Add-AzureAccount
   ```

   These credentials expire after a period of time and you have to re-run the `Add-AzureAccount` cmdlet. As this e-book is being written, the time limit before credentials expire is 12 hours.

5. If you have multiple subscriptions, use the Select-AzureSubscription cmdlet to specify the subscription you want to create the test environment in.

6. Import a management certificate for the same Azure subscription by using the `Get-AzurePublishSettingsFile` and `Import-AzurePublishSettingsFile` cmdlets. The first of these cmdlets downloads a certificate file, and in the second one you specify the location of that file in order to import it.
   > [!IMPORTANT]

   > Keep the downloaded file in a safe location or delete it when you're done with it, because it contains a certificate that can be used to manage your Azure services.

   ```
   PS C:\Users\username\Documents\Visual Studio 2013\Projects\MyFixIt\Automation> Get-
   AzurePublishSettingsFile
   PS C:\Users\username\Documents\Visual Studio 2013\Projects\MyFixIt\Automation> Import-
   AzurePublishSettingsFile "C:\Users
   \username\Downloads\Azure MSDN - Visual Studio Ultimate-12-14-2013-credentials.publishsettings"
   ```

The certificate is used for a REST API call that detects the development machine's IP address in order to set a firewall rule on the SQL Database server.

7. Run the Set-Location cmdlet (aliases are `cd`, `chdir`, and `sl`) to navigate to the directory that contains the scripts. (They're located in the *Automation* folder in the Fix It solution folder.) Put the path in quotes if any of the directory names contain spaces. For example, to navigate to the `c:\Sample Apps\FixIt\Automation` directory you could enter the following command:

```
PS C:\> cd "c:\Sample Apps\MyFixIt\Automation"
```

8. To allow Windows PowerShell to run these scripts, use the Unblock-File cmdlet. (The scripts are blocked because they were downloaded from the Internet.)

> **WARNING**
> Security - Before running `Unblock-File` on any script or executable file, open the file in Notepad, examine the commands, and verify that they do not contain any malicious code.

For example, the following command runs the `Unblock-File` cmdlet on all scripts in the current directory.

```
PS C:\Sample Apps\FixIt\Automation> Unblock-File -Path .\*.ps1
```

9. To create the web app for the base (no queues processing) Fix It app, run the environment creation script.

The required `Name` parameter specifies the name of the database and is also used for the storage account that the script creates. The name must be globally unique within the azurewebsites.net domain. If you specify a name that is not unique, like Fixit or Test (or even as in the example, fixitdemo), the `New-AzureWebsite` cmdlet fails with an Internal Error that reports a conflict. The script converts the name to all lower-case to comply with name requirements for web apps, storage accounts, and databases.

The required `SqlDatabasePassword` parameter specifies the password for the admin account that will be created for SQL Database. Don't include special XML characters in the password (& < > ;). This is a limitation of the way the scripts were written, not a limitation of Azure.

For example, if you want to create a web app named "fixitdemo" and use a SQL Server administrator password of "Passw0rd1", you could enter the following command:

```
PS C:\Sample Apps\FixIt\Automation> .\New-AzureWebsiteEnv.ps1 -Name
fixitdemo <required params here>
```

The name must be unique in the azurewebsites.net domain, and the password must meet SQL Database requirements for password complexity. (The example Passw0rd1 does meet the requirements.)

Note that the command begins with ".". To help prevent malicious execution of scripts, Windows PowerShell requires that you provide the fully qualified path to the script file when you run a script. You can use a dot to indicate the current directory (".") or provide the fully qualified path, such as:

```
PS C:\Temp\FixIt\Automation> C:\Temp\FixIt\Automation\New-AzureWebsiteEnv.ps1 -Name fixitdemo -
SqlDatabasePassword Pas$w0rd
```

For more information about the script, use the `Get-Help` cmdlet.

```
PS C:\Sample Apps\FixIt\Automation> Get-Help -Full .\New-AzureWebsiteEnv.ps1
```

You can use the `Detailed`, `Full`, `Parameters`, and `Examples` parameters of the Get-Help cmdlet to filter the help that is returned.

If the script fails or generates errors, such as "New-AzureWebsite : Call Set-AzureSubscription and Select-AzureSubscription first," you might not have completed the configuration of Azure PowerShell.

After the script finishes, you can use the Azure Management Portal to see the resources that were created, as shown in the Automate Everything chapter.

10. To deploy the FixIt project to the new Azure environment, use the *AzureWebsite.ps1* script. For example:

```
PS C:\Sample Apps\FixIt\Automation> .\Publish-AzureWebsite.ps1 ..\MyFixIt\MyFixIt.csproj -Launch
```

When deployment is done, the browser opens with Fix It running in Azure.

Troubleshooting the Windows PowerShell scripts

The most common errors encountered when running these scripts are related to permissions. Make sure that `Add-AzureAccount` and `Import-AzurePublishSettingsFile` were successful and that you used them for the same Azure subscription. Even if `Add-AzureAccount` was successful you might have to run it again. The permissions added by `Add-AzureAccount` expire in 12 hours.

Object reference not set to an instance of an object.

If the script returns errors, such as "Object reference not set to an instance of an object," which means that Windows PowerShell can't find an object to process (this is a null reference exception), run the `Add-AzureAccount` cmdlet and try the script again.

```
New-AzureSqlDatabaseServer : Object reference not set to an instance of an object.
At C:\ps-test\azure-powershell-samples-master\WebSite\create-azure-sql.ps1:80 char:19
+ $databaseServer = New-AzureSqlDatabaseServer -AdministratorLogin $UserName -Admi ...
~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
+ CategoryInfo          : NotSpecified: (:) [New-AzureSqlDatabaseServer], NullReferenceException
    + FullyQualifiedErrorId :
Microsoft.WindowsAzure.Commands.SqlDatabase.Server.Cmdlet.NewAzureSqlDatabaseServer
```

InternalError: The server encountered an internal error.

The `New-AzureWebsite` cmdlet returns an internal error when the name is not unique in the azurewebsites.net domain. To resolve the error, use a different value for the name, which is in the Name parameter of *New-AzureWebsiteEnv.ps1*.

```
New-AzureWebsite : InternalError: The server encountered an internal error.
Please retry the request.
At line:1 char:1
+ New-AzureWebsite -Name fixitdemo
+ ~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
+ CategoryInfo
: CloseError: (:) [New-AzureWebsite], Exception
+ FullyQualifiedErrorId :
Microsoft.WindowsAzure.Commands.Websites.NewAzureWebsiteCommand
```

Restarting the script

If you need to restart the *New-AzureWebsiteEnv.ps1* script because it failed before it printed the "Script is

complete" message, you might want to delete resources that the script created before it stopped. For example, if the script already created the ContosoFixItDemo web app and you run the script again with the same name, the script will fail because the name is in use.

To determine which resources the script created before it stopped, use the following cmdlets:

- `Get-AzureWebsite`
- `Get-AzureSqlDatabaseServer`
- `Get-AzureSqlDatabase`: To run this cmdlet, pipe the database server name to `Get-AzureSqlDatabase`: `Get-AzureSqlDatabaseServer | Get-AzureSqlDatabase.`

To delete these resources, use the following commands. Note that if you delete the database server, you automatically delete the databases associated with the server.

- `Get-AzureWebsite -Name <WebsiteName> | Remove-AzureWebsite`
- `Get-AzureSqlDatabase -Name <DatabaseName> -ServerName <DatabaseServerName> | Remove-SqlAzureDatabase`
- `Get-AzureSqlDatabaseServer | Remove-AzureSqlDatabaseServer`

How to deploy the app with queue processing to Azure App Service Web Apps and an Azure Cloud Service

To enable queues, make the following change in the MyFixIt\Web.config file. Under `appSettings`, change the value of `UseQueues` to "true":

```
<appSettings>
    <!-- Other settings not shown -->
    <add key="UseQueues" value="true"/>
</appSettings>
```

Then deploy the MVC application to an web app in Azure App Service, as described earlier.

Next, create a new Azure cloud service. The scripts included with the Fix It app do not create or deploy the cloud service, so you must use Azure portal for this. In the portal, click **New** -- **Compute** – **Cloud Service** -- **Quick Create**, and then enter a URL and a data center location. Use the same data center where you deployed the web app.

Before you can deploy the cloud service, you need to update some of the configuration files.

In MyFixIt.WorkerRole\app.config, under `connectionStrings`, replace the value of the `appdb` connection string with the actual connection string for the SQL Database. You can get the connection string from the portal. In the portal, click **SQL Databases** - **appdb** - **View SQL Database connection strings for ADO .Net, ODBC, PHP, and JDBC**. Copy the ADO.NET connection string and paste the value into the app.config file. Replace "

{your_password_here}" with your database password. (Assuming you used the scripts to deploy the MVC app, you specified the database password in the `SqlDatabasePassword` script parameter.)

The result should look like the following:

```
<add name="appdb" connectionString="Server=tcp:####.database.windows.net,1433;Database=appdb;User
ID=####;Password=####;Trusted_Connection=False;Encrypt=True;Connection Timeout=30;"
providerName="System.Data.SqlClient" />
```

In the same MyFixIt.WorkerRole\app.config file, under `appSettings`, replace the two placeholder values for the Azure storage account.

```
<appSettings>
  <add key="StorageAccountName" value="{StorageAccountName}" />
  <add key="StorageAccountAccessKey" value="{StorageAccountAccessKey}" />
</appSettings>
```

You can get the access key from the portal. See How To Manage Storage Accounts.

In MyFixItCloudService\ServiceConfiguration.Cloud.cscfg, replace the same two placeholders values for the Azure storage account.

```
<ConfigurationSettings>
    <Setting name="Microsoft.WindowsAzure.Plugins.Diagnostics.ConnectionString"
             value="DefaultEndpointsProtocol=https;AccountName={StorageAccountName};AccountKey=
{StorageAccountAccessKey}" />
  </ConfigurationSettings>
```

Now you are ready to deploy the cloud service. In Solution Explore, right-click the MyFixItCloudService project and select **Publish**. For more information, see "Deploy the Application to Azure", which is in part 2 of this tutorial.

Hands on Lab: Maintainable Azure Websites: Managing Change and Scale

2/20/2020 • 34 minutes to read • Edit Online

by Web Camps Team

Download Web Camps Training Kit

Microsoft Azure makes it easy to build and deploy websites to production. But you're not done when your application is live, you're just getting started! You'll need to handle changing requirements, database updates, scale, and more. Fortunately, Azure App Service has you covered, with plenty of features to help you keep your sites running smoothly.

Azure offers secure and flexible development, deployment and scaling options for any size web application. Leverage your existing tools to create and deploy applications without the hassle of managing infrastructure.

Provision a production web application yourself in minutes by easily deploying content created using your favorite development tool. You can deploy an existing site directly from source control with support for **Git**, **GitHub**, **Bitbucket**, **TFS**, and even **DropBox**. Deploy directly from your favorite IDE or from scripts using **PowerShell** in Windows or **CLI** tools running on any OS. Once deployed, keep your sites constantly up-to-date with support for continuous deployment.

Azure provides scalable, durable cloud storage, backup, and recovery solutions for any data, big or small. When deploying applications to a production environment, storage services such as Tables, Blobs and SQL Databases, help you scale your application in the cloud.

With SQL Databases, it is important to keep your productive database up-to-date when deploying new versions of your application. Thanks to **Entity Framework Code First Migrations**, the development and deployment of your data model has been simplified to update your environments in minutes. This hands-on lab will show you the different topics you could encounter when deploying your web app to production environments in Microsoft Azure.

All sample code and snippets are included in the Web Camps Training Kit, available at https://aka.ms/webcamps-training-kit.

For more in-depth coverage of this topic, see the Building Real-World Cloud Apps with Azure e-book.

Overview

Objectives

In this hands-on lab, you will learn how to:

- Enable Entity Framework Migrations with an existing model
- Update the object model and database accordingly using Entity Framework Migrations
- Deploy to Azure App Service using Git
- Rollback to a previous deployment using the Azure Management portal
- Use Azure Storage to scale a web app
- Configure auto-scaling for a web app using the Azure Management Portal
- Create and configure a load test project in Visual Studio

Prerequisites

The following is required to complete this hands-on lab:

- Visual Studio Express 2013 for Web or greater
- Azure SDK for .NET 2.2
- GIT Version Control System
- A Microsoft Azure subscription
  - Sign up for a Free Trial
  - If you are a Visual Studio Professional, Test Professional, Premium or Ultimate with MSDN or MSDN Platforms subscriber, activate your MSDN benefit now to start developing and testing on Azure
  - BizSpark members automatically receive the Azure benefit through their Visual Studio Ultimate with MSDN subscriptions
  - Members of the Microsoft Partner Network Cloud Essentials program receive monthly Azure credits at no charge

Setup

In order to run the exercises in this hands-on lab, you will need to set up your environment first.

1. Open Windows Explorer and browse to the lab's **Source** folder.
2. Right-click on **Setup.cmd** and select **Run as administrator** to launch the setup process that will configure your environment and install the Visual Studio code snippets for this lab.
3. If the User Account Control dialog is shown, confirm the action to proceed.

> **NOTE**
> Make sure you have checked all the dependencies for this lab before running the setup.

Using the Code Snippets

Throughout the lab document, you will be instructed to insert code blocks. For your convenience, most of this code is provided as Visual Studio Code Snippets, which you can access from within Visual Studio 2013 to avoid having to add it manually.

> **NOTE**
> Each exercise is accompanied by a starting solution located in the **Begin** folder of the exercise that allows you to follow each exercise independently of the others. Please be aware that the code snippets that are added during an exercise are missing from these starting solutions and may not work until you have completed the exercise. Inside the source code for an exercise, you will also find an **End** folder containing a Visual Studio solution with the code that results from completing the steps in the corresponding exercise. You can use these solutions as guidance if you need additional help as you work through this hands-on lab.

Exercises

This hands-on lab includes the following exercises:

1. Using Entity Framework Migrations
2. Deploying a Web App to Staging
3. Performing Deployment Rollback in Production
4. Scaling Using Azure Storage
5. Using Autoscale for Web Apps (Optional for Visual Studio 2013 Ultimate edition)

Estimated time to complete this lab: **75 minutes**

> **NOTE**
>
> When you first start Visual Studio, you must select one of the predefined settings collections. Each predefined collection is designed to match a particular development style and determines window layouts, editor behavior, IntelliSense code snippets, and dialog box options. The procedures in this lab describe the actions necessary to accomplish a given task in Visual Studio when using the **General Development Settings** collection. If you choose a different settings collection for your development environment, there may be differences in the steps that you should take into account.

Exercise 1: Using Entity Framework Migrations

When you are developing an application, your data model might change over time. These changes could affect the existing model in your database (if you are creating a new version) and it is important to keep your database up-to-date to prevent errors.

To simplify the tracking of these changes in your model, **Entity Framework Code First Migrations** automatically detect changes comparing your model with the database schema and generates specific code to update your database, creating new *versions* of your database.

This exercise shows you how to enable **Migrations** for your application and how you can easily detect and generate changes to update your databases.

Task 1 – Enabling Migrations

In this task, you will go through the steps of enabling **Entity Framework Code First Migrations** to the **Geek Quiz** database, changing the model and understanding how those changes are reflected in the database.

1. Open Visual Studio and open the **GeekQuiz.sln** solution file from **Source\Ex1-UsingEntityFrameworkMigrations\Begin**.
2. Build the solution in order to download and install the **NuGet** package dependencies. To do this, right-click the solution and click **Build Solution** or press **Ctrl + Shift + B**.
3. From the **Tools** menu in Visual Studio, select **NuGet Package Manager**, and then click **Package Manager Console**.
4. In the **Package Manager Console**, enter the following command and then press **Enter**. An initial migration based on the existing model will be created.

```
Enable-Migrations -ContextTypeName GeekQuiz.Models.TriviaContext
```

Enabling Migrations

> **NOTE**
>
> This command adds a **Migrations** folder to Geek Quiz project that contains a file called **Configuration.cs**. The **Configuration** class allows you to configure how Migrations behaves for your context.

5. With Migrations enabled, you need to update the **Configuration** class to populate the database with the initial data that **Geek Quiz** requires. Under **Migrations**, replace the **Configuration.cs** file with the one located in the **Source\Assets** folder of this lab.

> **NOTE**
>
> Since **Migrations** will call the **Seed** method with every database update, you need to be sure that records are not duplicated in the database. The **AddOrUpdate** method will help to prevent duplicate data.

6. To add an initial migration, enter the following command and then press **Enter**.

> **NOTE**
>
> Make sure that there is no database named "GeekQuizProd" in your LocalDB instance.

```
Add-Migration InitialSchema
```

Adding base schema migration

> **NOTE**
>
> **Add-Migration** will scaffold the next migration based on changes you have made to your model since the last migration was created. In this case, as it is the first migration of the project, it will add the scripts to create all the tables defined in the **TriviaContext** class.

7. Execute the migration to update the database by running the following command. For this command you will specify the **Verbose** flag to view the SQL statements being applied to the target database.

```
Update-Database -Verbose
```

```
Package Manager Console
Package source: nuget.org    Default project: GeekQuiz
PM> Update-Database -Verbose
Using Startup project 'GeekQuiz'.
Using NuGet project 'GeekQuiz'.
Specify the '-Verbose' flag to view the SQL statements being applied to the target database.
Target database is: 'GeekQuizProd' (DataSource: (LocalDb)\v11.0, Provider: System.Data.SqlClient, Origin: Configuration).
Applying explicit migrations: [201402271418493_InitialSchema].
Applying explicit migration: 201402271418493_InitialSchema.
CREATE TABLE [dbo].[TriviaAnswers] (
    [QuestionId] [int] NOT NULL,
    [OptionId] [int] NOT NULL,
    [Id] [int] NOT NULL IDENTITY,
    [UserId] [nvarchar](max),
    CONSTRAINT [PK_dbo.TriviaAnswers] PRIMARY KEY ([Id])
)
CREATE INDEX [IX_QuestionId_OptionId] ON [dbo].[TriviaAnswers]([QuestionId], [OptionId])
CREATE TABLE [dbo].[TriviaOptions] (
    [QuestionId] [int] NOT NULL,
    [Id] [int] NOT NULL IDENTITY,
    [Title] [nvarchar](max) NOT NULL,
    [IsCorrect] [bit] NOT NULL,
    CONSTRAINT [PK_dbo.TriviaOptions] PRIMARY KEY ([QuestionId], [Id])
)
CREATE INDEX [IX_QuestionId] ON [dbo].[TriviaOptions]([QuestionId])
CREATE TABLE [dbo].[TriviaQuestions] (
    [Id] [int] NOT NULL IDENTITY,
    [Title] [nvarchar](max) NOT NULL,
    CONSTRAINT [PK_dbo.TriviaQuestions] PRIMARY KEY ([Id])
)
ALTER TABLE [dbo].[TriviaAnswers] ADD CONSTRAINT [FK_dbo.TriviaAnswers_dbo.TriviaOptions_QuestionId_OptionId] FOREIGN KEY
([QuestionId], [OptionId]) REFERENCES [dbo].[TriviaOptions] ([QuestionId], [Id]) ON DELETE CASCADE
ALTER TABLE [dbo].[TriviaOptions] ADD CONSTRAINT [FK_dbo.TriviaOptions_dbo.TriviaQuestions_QuestionId] FOREIGN KEY ([QuestionId])
REFERENCES [dbo].[TriviaQuestions] ([Id]) ON DELETE CASCADE
CREATE TABLE [dbo].[__MigrationHistory] (
    [MigrationId] [nvarchar](150) NOT NULL,
    [ContextKey] [nvarchar](300) NOT NULL,
    [Model] [varbinary](max) NOT NULL,
    [ProductVersion] [nvarchar](32) NOT NULL,
    CONSTRAINT [PK_dbo.__MigrationHistory] PRIMARY KEY ([MigrationId], [ContextKey])
)
100 %
```

Creating initial database

> **NOTE**
>
> **Update-Database** will apply any pending migrations to the database. In this case, it will create the database using the connection string defined in your web.config file.

8. Go to **View** menu and open **SQL Server Object Explorer**.

Open in SQL Server Object Explorer

9. In the **SQL Server Object Explorer** window, connect to your LocalDB instance by right-clicking the **SQL Server** node and selecting **Add SQL Server...** option.

Adding a SQL Server instance to SQL Server Object Explorer

10. Set the **server name** to *(localdb)\v11.0* and leave **Windows Authentication** as your authentication mode. Click **Connect** to continue.

Connecting to LocalDB

11. Open the **GeekQuizProd** database and expand the **Tables** node. As you can see, the **Update-Database** command generated all the tables defined in the **TriviaContext** class. Locate the **dbo.TriviaQuestions** table and open the columns node. In the next task, you will add a new column to this table and update the database using **Migrations**.

Trivia Questions Columns

Task 2 – Updating Database Schema Using Migrations

In this task, you will use **Entity Framework Code First Migrations** to detect a change in your model and generate the necessary code to update the database. You will update the **TriviaQuestions** entity by adding a new

property to it. Then you will run commands to create a new Migration to include the new column in the table.

1. In **Solution Explorer**, double-click the **TriviaQuestion.cs** file located inside the **Models** folder.
2. Add a new property named **Hint**, as shown in the following code snippet.

```
public class TriviaQuestion
{
     public int Id { get; set; }

     [Required]
     public string Title { get; set; }

     public virtual List<TriviaOption> Options { get; set; }

     public string Hint { get; set; }
}
```

3. In the **Package Manager Console**, enter the following command and then press **Enter**. A new migration will be created reflecting the change in our model.

```
Add-Migration QuestionHint
```

Add-Migration

> **NOTE**
>
> A Migration file is composed of two methods, **Up** and **Down**.
>
> - The **Up** method will be used to specify what changes the current version of our application need to apply to the database.
> - The **Down** is used to reverse the changes we have added to the **Up** method.
>
> When the Database Migration updates the database, it will run all migrations in the timestamp order, and only those that have not been used since the last update (The _MigrationHistory table keeps track of which migrations have been applied). The **Up** method of all migrations will be called and will make the changes we have specified to the database. If we decide to go back to a previous migration, the **Down** method will be called to redo the changes in a reverse order.

4. In the **Package Manager Console**, enter the following command and then press **Enter**.

```
Update-Database -Verbose
```

5. The output of the **Update-Database** command generated an **Alter Table** SQL statement to add a new column to the **TriviaQuestions** table, as shown in the image below.

Add column SQL statement generated

6. In **SQL Server Object Explorer**, refresh the **dbo.TriviaQuestions** table and check that the new **Hint** column is displayed.

Showing the new Hint Column

7. Back in the **TriviaQuestion.cs** editor, add a **StringLength** constraint to the *Hint* property, as shown in the following code snippet.

```
public class TriviaQuestion
{
     public int Id { get; set; }

     [Required]
     public string Title { get; set; }

     public virtual List<TriviaOption> Options { get; set; }

     [StringLength(150)]
     public string Hint { get; set; }
}
```

8. In the **Package Manager Console**, enter the following command and then press **Enter**.

```
Add-Migration QuestionHintLength
```

9. In the **Package Manager Console**, enter the following command and then press **Enter**.

```
Update-Database -Verbose
```

10. The output of the **Update-Database** command generated an **Alter Table** SQL statement to update the *hint* column type of the **TriviaQuestions** table, as shown in the image below.

Alter column SQL statement generated

11. In **SQL Server Object Explorer**, refresh the **dbo.TriviaQuestions** table and check that the **Hint** column type is **nvarchar(150)**.

Showing the new constraint

Exercise 2: Deploying a Web App to Staging

Web Apps in Azure App Service enables you to perform staged publishing. Staged publishing creates a staging site slot for each default production site and enables you to swap these slots with no down time. This is really useful to validate changes before releasing to the public, incrementally integrate site content, and roll back if changes are not working as expected.

In this exercise, you will deploy the **Geek Quiz** application to the staging environment of your web app using Git source control. To do this, you will create the web app and provision the required components at the management portal, configure a **Git** repository and push the application source code from your local computer to the staging slot. You will also update your production database with the **Code First Migrations** you created in the previous exercise. You will then execute the application in this test environment to verify its operation. Once you are satisfied that it is working according to your expectations, you will promote the application to production.

> **NOTE**
>
> To enable staged publishing, the web app must be in **Standard mode**. Note that additional charges will be incurred if you change your web app to Standard mode. For more information about pricing, see App Service Pricing.

Task 1 – Creating a Web App in Azure App Service

In this task, you will create a web app in **Azure App Service** from the management portal. You will also configure a **SQL Database** to persist the application data, and configure a local Git repository for source control.

1. Go to the Azure management portal and sign in using the Microsoft account associated with your subscription.

Sign in to the Azure management portal

2. Click **New** in the command bar at the bottom of the page.

Creating a new web app

3. Click **Compute**, **Website** and then **Custom Create**.

Creating a new web app using Custom Create

4. In the **New Website - Custom Create** dialog box, provide an available **URL** (e.g. *geek-quiz*), select a location in the **Region** drop-down list, and select **Create a new SQL database** in the **Database** drop-down list. Finally, select the **Publish from source control** check box and click **Next**.

Customizing the new web app

5. Specify the following information for the database settings:

   - In the **Name** text box, enter a database name (e.g. *geekquiz_db*)
   - In the Server **drop-down** list, select **New SQL database server**. Alternatively, you can select an existing server.
   - In the **Database username** and **Database password** boxes, enter the administrator username and password for the SQL database server. If you select a server you have already created, you will be prompted for the password.

Specifying the database settings

6. Click **Next** to continue.

7. Select **Local Git repository** for the source control to use and click **Next**.

> **NOTE**
>
> You may be prompted for the deployment credentials (a username and password).

Creating the Git repository

8. Wait until the new web app is created.

NOTE

By default, Azure provides domains at *azurewebsites.net* but also gives you the possibility to set custom domains using the Azure management portal. However, you can only manage custom domains if you are using certain Azure App Service modes.

Azure App Service is available in Free, Shared, Basic, Standard, and Premium editions. In Free and Shared mode, all web apps run in a multi-tenant environment and have quotas for CPU, Memory, and Network usage. The maximum number of free apps may vary with your plan. In Standard mode, you choose which apps run on dedicated virtual machines that correspond to the standard Azure compute resources. You can find the web app mode configuration in the **Scale** menu of your web app.

If you are using **Shared** or **Standard** mode, you will be able to manage custom domains for your web app by going to your app's **Configure** menu and clicking **Manage Domains** under *domain names*.

9. Once the web app is created, click the link under the **URL** column to check that the new web app is running.

Browsing to the new web app

web app running

Task 2 – Creating the Production SQL Database

In this task, you will use the **Entity Framework Code First Migrations** to create the database targeting the **Azure SQL Database** instance you created in the previous task.

1. In the Management Portal, navigate to the web app you created in the previous task and go to its **Dashboard**.
2. In the **Dashboard** page, click **View connection strings** link under the **quick glance** section.

View connection strings

3. Copy the **connection string** value and close the dialog box.

Connection String in Azure Management Portal

4. Click **SQL Databases** to see the list of SQL databases in Azure

SQL Database menu

5. Locate the database you created in the previous task and click on the Server.

SQL Database server

6. In the **Quick Start** page of the server, click on **Configure**.

Configure menu

7. In the **Allowed IP addresses** section, click on **Add to the allowed IP addresses** link to enable your IP to connect to the SQL Database server.

Allowed IP addresses

8. Click **Save** at the bottom of the page to complete the step.

9. Switch back to Visual Studio.

10. In the **Package Manager Console**, execute the following command replacing *[YOUR-CONNECTION-STRING]* placeholder with the connection string you copied from Azure

```
Update-Database -Verbose -ConnectionString "[YOUR-CONNECTION-STRING]" -ConnectionProviderName
"System.Data.SqlClient"
```

Update database targeting Azure SQL Database

Task 3 – Deploying Geek Quiz to Staging Using Git

In this task, you will enable staged publishing in your web app. Then, you will use Git to publish the Geek Quiz application directly from your local computer to the staging environment of your web app.

1. Go back to the portal and click the name of the web app under the **Name** column to display the management pages.

Opening the web app management pages

2. Navigate to the **Scale** page. Under the **general** section, select **Standard** for the configuration and click **Save** in the command bar.

> **NOTE**
>
> To run all web apps in the current region and subscription in **Standard** mode, leave the **Select All** check box selected in the **Choose Sites** configuration. Otherwise, clear the **Select All** check box.

Upgrading the Web App to Standard mode

3. Click **Yes** to confirm the changes.

Confirming the change to Standard mode

4. Go to the **Dashboard** page and click **Enable staged publishing** under the **quick glance** section.

Enabling staged publishing

5. Click **Yes** to enable staged publishing.

Confirming staged publishing

6. In the list of web apps, expand the mark to the left of your web app name to display the staging site slot. It has the name of your web app followed by ***(staging)***. Click the staging site to go to the management page.

Navigating to the staging app

7. Notice that he management page looks like any other web app's management page. Navigate to the **Deployments** page and copy the **Git URL** value. You will use it later in this exercise.

Copying the Git URL value

8. Open a new **Git Bash** console and execute the following commands. Update the *[YOUR-APPLICATION-PATH]* placeholder with the path to the **GeekQuiz** solution, located in the **Source\Ex1-DeployingWebSiteToStaging\Begin** folder of this lab.

```
cd "[YOUR-APPLICATION-PATH]"
git init
git config --global user.email "{username@example.com}"
git config --global user.name "{your-user-name}"
git add .
git commit -m "Initial commit"
```

Git initialization and first commit

9. Run the following command to push your web app to the remote **Git** repository. Replace the placeholder with the URL you obtained from the management portal. You will be prompted for your deployment password.

```
git remote add azure [GIT-CLONE-URL]
git push azure master
```

```

Demo@WIN81RTM /c/Projects/GeekQuiz (master)
$ git remote add azure https://admin01@geek-quiz-staging.scm.azurewebsites.ne
t:443/geek-quiz.git

Demo@WIN81RTM /c/Projects/GeekQuiz (master)
$ git push azure master
Password for 'https://admin01@geek-quiz-staging.scm.azurewebsites.net:443'
```

Pushing to Azure

> **NOTE**
>
> When you deploy content to the FTP host or GIT repository of a web app, you must authenticate using the **deployment credentials** that you created from the web app's **Quick Start** or **Dashboard** management pages. If you do not know your deployment credentials you can easily reset them using the management portal. Open the web app **Dashboard** page and click the **Reset your deployment credentials** link. Provide a new password and click **OK**. Deployment credentials are valid for use with all web apps associated with your subscription.

10. In order to verify the web app was successfully pushed to Azure, go back to the management portal and click **Websites**.

11. Locate your web app and expand the entry to display the staging site slot. Click its **Name** to go to the management page.

12. Click **Deployments** to see the **deployment history**. Verify that there is an **Active Deployment** with your *"Initial Commit"*.

Active deployment

13. Finally, click **Browse** in the command bar to go to the web app.

Browse web app

14. If the application is successfully deployed, you will see the Geek Quiz login page.

> **NOTE**
>
> The address URL of the deployed application contains the name of your web app followed by *-staging*.

Application running in the staging environment

15. If you wish to explore the application, click **Register** to register a new user. Complete the account details by entering a user name, email address and password. Next, the application shows the first question of the quiz. Answer a few questions to make sure it is working as expected.

Application ready to be used

Task 4 – Promoting the Web App to Production

Now that you have verified that the web app is working correctly in the staging environment, you are ready to

promote it to production. In this task, you will swap the staging site slot with the production site slot.

1. Go back to the management portal and select the staging site slot. Click **Swap** in the command bar.

Swap to production

2. Click **Yes** in the confirmation dialog box to proceed with the swap operation. Azure will immediately swap the content of the production site with the content of the staging site.

> **NOTE**
>
> Some settings from the staged version will automatically be copied to the production version (e.g. connection string overrides, handler mappings, etc.) but other settings will not change (e.g. DNS endpoints, SSL bindings, etc.).

Confirming swap operation

3. Once the swap is complete, select the production slot and click **Browse** in the command bar to open the production site. Notice the URL in the address bar.

> **NOTE**
>
> You might need to refresh your browser to clear cache. In Internet Explorer, you can do this by pressing **CTRL+R**.

4. In the **GitBash** console, update the remote URL for the local Git repository to target the production slot. To do this, run the following command replacing the placeholders with your deployment username and the name of your web app.

> **NOTE**
>
> In the following exercises, you will push changes to the production site instead of staging just for the simplicity of the lab. In a real-world scenario, it is recommended to verify the changes in the staging environment before promoting to production.

```
git remote set-url azure https://<your-user>@<your-web-site>.scm.azurewebsites.net:443/<your-web-site>.git
```

Exercise 3: Performing Deployment Rollback in Production

There are scenarios where you do not have a staging slot to perform hot swap between staging and production, for example, if you are working with **Free** or **Shared** mode. In those scenarios, you should test your application in a testing environment –either locally or in a remote site– before deploying to production. However, it is possible that an issue not detected during the testing phase may arise in the production site. In this case, it is important to have a mechanism to easily switch to a previous and more stable version of the application as quickly as possible.

In **Azure App Service**, continuous deployment from source control makes this possible thanks to the **redeploy** action available in the management portal. Azure keeps track of the deployments associated with the commits pushed to the repository and provides an option to redeploy your application using any of your previous deployments, at any time.

In this exercise you will perform a change to the code in the **Geek Quiz** application that intentionally injects a *bug*. You will deploy the application to production to see the error, and then you will take advantage of the redeploy feature to go back to the previous state.

Task 1 – Updating the Geek Quiz Application

In this task, you will refactor a small piece of code of the **TriviaController** class to extract part of the logic that retrieves the selected quiz option from the database into a new method.

1. Switch to the Visual Studio instance with the **GeekQuiz** solution from the previous exercise.
2. In **Solution Explorer**, open the **TriviaController.cs** file inside the **Controllers** folder.
3. Locate the **StoreAsync** method and select the code highlighted in the following figure.

```
private async Task<bool> StoreAsync(TriviaAnswer answer)
{
    this.db.TriviaAnswers.Add(answer);

    await this.db.SaveChangesAsync();
    var selectedOption = await this.db.TriviaOptions.FirstOrDefaultAsync(o => o.Id == answer.OptionId
        && o.QuestionId == answer.QuestionId);

    return selectedOption.IsCorrect;
}
```

Selecting the code

4. Right-click the selected code, expand the **Refactor** menu and select **Extract Method...**.

Selecting Extract Method

5. In the **Extract Method** dialog box, name the new method *MatchesOption* and click **OK**.

Specifying the name for the extracted method

6. The selected code is then extracted into the **MatchesOption** method. The resulting code is shown in the following snippet.

```
private async Task<bool> StoreAsync(TriviaAnswer answer)
{
    this.db.TriviaAnswers.Add(answer);

    await this.db.SaveChangesAsync();
    var selectedOption = await this.db.TriviaOptions.FirstOrDefaultAsync(o => MatchesOption(answer, o));

    return selectedOption.IsCorrect;
}

private static bool MatchesOption(TriviaAnswer answer, TriviaOption o)
{
    return o.Id == answer.OptionId
            && o.QuestionId == answer.QuestionId;
}
```

7. Press **CTRL + S** to save the changes.

Task 2 – Redeploying the Geek Quiz Application

You will now push the changes you made in the previous task to the repository, which will trigger a new deployment to the production environment. Then, you will troubleshot an issue using the **F12 development tools** provided by Internet Explorer, and then perform a rollback to the previous deployment from the Azure management portal.

1. Open a new **Git Bash** console to deploy the updated application to Azure App Service.

2. Execute the following commands to push the changes to Azure. Update the *[YOUR-APPLICATION-PATH]* placeholder with the path to the **GeekQuiz** solution. You will be prompted for your deployment password.

```
cd "[YOUR-APPLICATION-PATH]"
git add .
git commit -m "Refactored answer check"
git push azure master
```

```
Demo@WIN81RTM /c/Projects/GeekQuiz (master)
$ git add .

Demo@WIN81RTM /c/Projects/GeekQuiz (master)
$ git commit -m "Refactored answer check"
[master c7a7de7] Refactored answer check
 1 file changed, 7 insertions(+), 2 deletions(-)

Demo@WIN81RTM /c/Projects/GeekQuiz (master)
$ git push azure master
Password for 'https://admin01@geek-quiz.scm.azurewebsites.net:443': _
```

Pushing refactored code to Azure

3. Open Internet Explorer and navigate to your web app (e.g. `http://<your-web-site>.azurewebsites.net`). Log in using the previously created credentials.

4. Press **F12** to launch the development tools, select the **Network** tab and click the **Play** button to start recording.

Starting network recording

5. Select any option of the quiz. You will see that nothing happens.

6. In the **F12** window, the entry corresponding to the POST HTTP request shows an HTTP **500** result.

HTTP 500 error

7. Select the **Console** tab. An error is logged with the details of the cause.

Logged error

8. Locate the details part of the error. Clearly, this error is caused by the code refactoring you committed in the previous steps.

```
Details: LINQ to Entities does not recognize the method 'Boolean MatchesOption ...
```

9. Do not close the browser.

10. In a new browser instance, navigate to the Azure management portal and sign in using the Microsoft account associated with your subscription.

11. Select **Websites** and click the web app you created in Exercise 2.

12. Navigate to the **Deployments** page. Notice that all the commits performed are listed in the deployment history.

List of existing deployments

13. Select the previous commit and click **Redeploy** on the command bar.

Redeploying the previous commit

14. When prompted to confirm, click **Yes**.

15. When the deployment completes, switch back to the browser instance with your web app and press **CTRL + F5**.

16. Click any of the options. The flip animation will now take place and the result (*correct/incorrect*) will be displayed.

17. (Optional) Switch to the **Git Bash** console and execute the following commands to revert to the previous commit.

> **NOTE**
>
> These commands create a new commit that undoes all changes in the Git repository that were made in the bad commit. Azure will then redeploy the application using the new commit.

```
git revert HEAD --no-edit
git push azure master
```

Exercise 4: Scaling Using Azure Storage

Blobs are the simplest way to store large amounts of unstructured text or binary data such as video, audio and images. Moving the static content of your application to Storage, helps to scale your application by serving images or documents directly to the browser.

In this exercise, you will move the static content of your application to a Blob container. Then you will configure your application to add an **ASP.NET URL rewrite rule** in the **Web.config** to redirect your content to the Blob container.

Task 1 – Creating an Azure Storage Account

In this task you will learn how to create a new storage account using the management portal.

1. Navigate to the Azure management portal and sign in using the Microsoft account associated with your subscription.

2. Select **New | Data Services | Storage | Quick Create** to start creating a new storage account. Enter a

unique name for the account and select a **Region** from the list. Click **Create Storage Account** to continue.

Creating a new storage account

3. In the **Storage** section, wait until the status of the new storage account changes to *Online* in order to continue with the following step.

Storage Account created

4. Click on the storage account name and then click the **Dashboard** link at the top of the page. The **Dashboard** page provides you with information about the status of the account and the service endpoints that can be used within your applications.

Displaying the Storage Account Dashboard

5. Click the **Manage Access Keys** button in the navigation bar.

Manage Access Keys button

6. In the **Manage Access Keys** dialog box, copy the **Storage Account Name** and **Primary Access Key** as you will need them in the following exercise. Then, close the dialog box.

Manage Access Key dialog box

Task 2 – Uploading an Asset to Azure Blob Storage

In this task, you will use the Server Explorer window from Visual Studio to connect to your storage account. You will then create a blob container and upload a file with the Geek Quiz logo to the container.

1. Switch to the Visual Studio instance with the **GeekQuiz** solution from the previous exercise.

2. From the menu bar, select **View** and then click **Server Explorer**.

3. In **Server Explorer**, right-click the **Azure** node and select **Connect to Azure...**. Sign in using the Microsoft account associated with your subscription.

Connect to Azure

4. Expand the **Azure** node, right-click **Storage** and select **Attach External Storage...**.

5. In the **Add New Storage Account** dialog box, enter the **Account name** and **Account key** you obtained in the previous task and click **OK**.

Add New Storage Account dialog box

6. Your storage account should appear under the **Storage** node. Expand your storage account, right-click **Blobs** and select **Create Blob Container...**.

Create Blob Container

7. In the **Create Blob Container** dialog box, enter a name for the blob container and click **OK**.

Create Blob Container dialog box

8. The new blob container should be added to the **Blobs** node. Change the access permissions in the container to make the container public. To do this, right-click the **images** container and select **Properties**.

Images container properties

9. In the **Properties** window, set the **Public Read Access** to **Container**.

Changing public read access property

10. When prompted if you are sure you want to change the public access property, click **Yes**.

Microsoft Visual Studio warning

11. In **Server Explorer**, right-click in the **images** blob container and select **View Blob Container**.

View Blob Container

12. The images container should open in a new window and a legend with no entries should be shown. Click the **upload** icon to upload a file to the blob container.

Images container with no entries

13. In the **Upload Blob** dialog box, navigate to the **Assets** folder of the lab. Select the **logo-big.png** file and click **Open**.

14. Wait until the file is uploaded. When the upload completes, the file should be listed in the images container. Right-click the file entry and select **Copy URL**.

Copy blob URL

15. Open Internet Explorer and paste the URL. The following image should be shown in the browser.

logo-big.png image from Azure Blob Storage

Task 3 – Updating the Solution to Consume Static Content from Azure Blob Storage

In this task, you will configure the **GeekQuiz** solution to consume the image uploaded to Azure Blob Storage (instead of the image located in the web app) by adding an ASP.NET URL rewrite rule in the **web.config** file.

1. In Visual Studio, open the **Web.config** file inside the **GeekQuiz** project and locate the **<system.webServer>** element.

2. Add the following code to add an URL rewrite rule, updating the placeholder with your storage account name.

   (Code Snippet - *WebSitesInProduction - Ex4 - UrlRewriteRule*)

```
<system.webServer>
    <rewrite>
        <rules>
            <rule name="redirect-images" stopProcessing="true">
                <match url="img/(.*)"/>
                <action type="Redirect" url="http://[YOUR-STORAGE-
ACCOUNT].blob.core.windows.net/images/{R:1}"></action>
            </rule>
        </rules>
    </rewrite>
```

> **NOTE**
>
> URL rewriting is the process of intercepting an incoming Web request and redirecting the request to a different resource. The URL rewriting rules tells the rewriting engine when a request needs to be redirected, and where should they be redirected. A rewriting rule is composed of two strings: the pattern to look for in the requested URL (usually, using regular expressions), and the string to replace the pattern with, if found. For more information, see URL Rewriting in ASP.NET.

3. Press **CTRL + S** to save the changes.

4. Open a new **Git Bash** console to deploy the updated application to Azure App Service.

5. Execute the following commands to push the changes to Azure. Update the *[YOUR-APPLICATION-PATH]* placeholder with the path to the **GeekQuiz** solution. You will be prompted for your deployment password.

```
cd "[YOUR-APPLICATION-PATH]"
git add .
git commit -m "Added URL rewrite rule in web.config file"
git push azure master
```

Deploying update to Azure

Task 4 – Verification

In this task you will use **Internet Explorer** to browse the **Geek Quiz** application and check that the URL rewrite rule for images works and you are redirected to the image hosted on **Azure Blob Storage**.

1. Open Internet Explorer and navigate to your web app (e.g. `http://<your-web-site>.azurewebsites.net`). Log in using the previously created credentials.

Showing the Geek Quiz web app with the image

2. Press **F12** to launch the development tools, select the **Network** tab and start recording.

Starting network recording

3. Press **CTRL + F5** to refresh the web page.

4. Once the page has finished loading, you should see an HTTP request for the **/img/logo-big.png** URL with an HTTP **301** result (redirect) and another request for `http://[YOUR-STORAGE-ACCOUNT].blob.core.windows.net/images/logo-big.png` URL with a HTTP **200** result.

Verifying the URL redirect

Exercise 5: Using Autoscale for Web Apps

> **NOTE**
>
> This exercise is optional, since it requires support for Web Load & Performance Testing which is only available for **Visual Studio 2013 Ultimate Edition**. For more information on specific Visual Studio 2013 features, compare versions here.

Azure App Service Web Apps provides the Autoscale feature for web apps running in **Standard Mode**. Autoscale lets Azure automatically scale the instance count of your web app depending on the load. When Autoscale is enabled, Azure checks the CPU of your web app once every five minutes and adds instances as needed at that point in time. If the CPU usage is low, Azure will remove instances once every two hours to ensure that the performance of your web app is not degraded.

In this exercise you will go through the steps required to configure the **Autoscale** feature for the **Geek Quiz** web app. You will verify this feature by running a Visual Studio load test to generate enough CPU load on the application to trigger an instance upgrade.

Task 1 – Configuring Autoscale Based on the CPU Metric

In this task you will use the Azure management portal to enable the Autoscale feature for the web app you created in Exercise 2.

1. In the Azure management portal, select **Websites** and click the web app you created in Exercise 2.

2. Navigate to the **Scale** page. Under the **capacity** section, select **CPU** for the **Scale by Metric** configuration.

> **NOTE**
>
> When scaling by CPU, Azure dynamically adjusts the number of instances that the app uses if the CPU usage changes.

Selecting to scale by CPU

3. Change the **Target CPU** configuration to **20-40** percent.

> **NOTE**
>
> This range represents the average CPU usage for your web app. Azure will add or remove instances to keep your web app in this range. The minimum and maximum number of instances used for scaling is specified in the **Instance Count** configuration. Azure will never go above or beyond that limit.
>
> The default **Target CPU** values are modified just for the purposes of this lab. By configuring the CPU range with small values, you are increasing the chances to trigger Autoscale when a moderate load is placed on the application.

Changing the Target CPU to be between 20 and 40 percent

4. Click **Save** in the command bar to save the changes.

Task 2 – Load Testing with Visual Studio

Now that **Autoscale** has been configured, you will create a **Web Performance and Load Test Project** in Visual Studio to generate some CPU load on your web app.

1. Open **Visual Studio Ultimate 2013** and select **File | New | Project...** to start a new solution.

Creating a new project

2. In the **New Project** dialog box, select **Web Performance and Load Test Project** under the **Visual C# | Test** tab. Make sure **.NET Framework 4.5** is selected, name the project *WebAndLoadTestProject*, choose a **Location** and click **OK**.

Creating a new Web and Load Test project

3. In the **WebTest1.webtest** Right-click the **WebTest1** node and click **Add Request**.

Adding a request to WebTest1

4. In the **Properties** window of the new request node, update the **Url** property to point to the URL of your web app (e.g. *http://geek-quiz.azurewebsites.net/*).

Changing the Url property

5. In the **WebTest1.webtest** window, right-click **WebTest1** and click **Add Loop...**.

Adding a loop to WebTest1

6. In the **Add Conditional Rule and Items to Loop** dialog box, select the **For Loop** rule and modify the following properties.

   a. **Terminating value:** 1000

   b. **Context Parameter Name:** Iterator

   c. **Increment Value:** 1

Selecting the For Loop rule and updating the properties

7. Under the **Items in loop** section, select the request you created previously to be the first and last item for the loop. Click **OK** to continue.

Selecting the first and last items for the loop

8. In **Solution Explorer**, right-click the **WebAndLoadTestProject** project, expand the **Add** menu and select **Load Test...**.

Adding a Load Test to the WebAndLoadTestProject project

9. In the **New Load Test Wizard** dialog box, click **Next**.

New Load Test Wizard

10. In the **Scenario** page, select **Do not use think times** and click **Next**.

Selecting not to use think times

11. In the **Load Pattern** page, make sure that the **Constant Load** option is selected. Change the **User Count** setting to **250** users and click **Next**.

Changing the user count to 250

12. In the **Test Mix Model** page, select **Based on sequential test order** and click **Next**.

Selecting the test mix model

13. In the **Test Mix Model** page, click **Add...** to add a test to the mix.

Adding a test to the test mix

14. In the **Add Tests** dialog box, double-click **WebTest1** to add the test to the **Selected tests** list. Click **OK** to continue.

Adding the WebTest1 test

15. Back in the **Test Mix** page, click **Next**.

Completing the Test Mix page

16. In the **Network Mix** page, click **Next**.

Clicking next in the Network Mix page

17. In the **Browser Mix** page, select **Internet Explorer 10.0** as the browser type and click **Next**.

Selecting the browser type

18. In the **Counter Sets** page, click **Next**.

Clicking Next in the Counter Sets page

19. In the **Run Settings** page, set the **Load test duration** to **5 minutes** and click **Finish**.

Setting the load test duration to 5 minutes

20. In **Solution Explorer**, double-click the **Local.settings** file to explore the test settings. By default, Visual Studio uses your local computer to run the tests.

> **NOTE**
>
> Alternatively, you can configure your test project to run the load tests in the cloud using **Azure Test Plans**. Azure Test Plans provides a cloud-based load testing service that simulates a more realistic load, avoiding local environment constraints like CPU capacity, available memory, and network bandwidth. For more information about using Azure Test Plans to run load tests, see Load testing scenarios.

Task 3 – Autoscale Verification

You will now execute the load test you created in the previous task and see how your web app behaves under load.

1. In **Solution Explorer**, double-click **LoadTest1.loadtest** to open the load test.

Opening LoadTest1.loadtest

2. In the **LoadTest1.loadtest** window, click the first button in the toolbox to run the load test.

Running the load test

3. Wait until the load test completes.

> **NOTE**
>
> The load test simulates multiple users that send requests to the web app simultaneously. When the test is running, you can monitor the available counters to detect any errors, warnings or other information related to your load test run.

Load test running

4. Once the test completes, go back to the management portal and navigate to the **Scale** page of your web app. Under the **capacity** section, you should see in the graph that a new instance was automatically deployed.

New instance automatically deployed

> **NOTE**
>
> It may take several minutes for the changes to appear in the graph (press **CTRL + F5** periodically to refresh the page). If you do not see any changes, you can try the following:
>
> - Increase the duration of the load test (e.g. to **10 minutes**)
> - Reduce the maximum and minimum values of the **Target CPU** range in the Autoscale configuration of your web app
> - Run the load test in the cloud with **Azure Test Plans**. More information here

---

Summary

In this hands-on lab, you learned how to set up and deploy your application to production web apps in Azure. You started by detecting and updating your databases using **Entity Framework Code First Migrations**, then continued by deploying new versions of your site using **Git** and performing rollbacks to the latest stable version of your site. Additionally, you learned how to scale your app using Storage to move your static content to a Blob container.

OWIN and Katana

2/20/2020 • 2 minutes to read • Edit Online

Katana is a flexible set of components for building and hosting Open Web Interface for .NET (OWIN)-based web applications.

An Overview of Project Katana

2/20/2020 • 21 minutes to read • Edit Online

by Howard Dierking

The ASP.NET Framework has been around for over ten years, and the platform has enabled the development of countless Web sites and services. As Web application development strategies have evolved, the framework has been able to evolve in step with technologies like ASP.NET MVC and ASP.NET Web API. As Web application development takes its next evolutionary step into the world of cloud computing, project Katana provides the underlying set of components to ASP.NET applications, enabling them to be flexible, portable, lightweight, and provide better performance – put another way, project Katana cloud optimizes your ASP.NET applications.

Why Katana – Why Now?

Regardless whether one is discussing a developer framework or end-user product, it's important to understand the underlying motivations for creating the product – and part of that includes knowing who the product was created for. ASP.NET was originally created with two customers in mind.

The first group of customers was classic ASP developers. At the time, ASP was one of the primary technologies for creating dynamic, data-driven Web sites and applications by interweaving markup and server-side script. The ASP runtime supplied server-side script with a set of objects that abstracted core aspects of the underlying HTTP protocol and Web server and provided access to additional services such session and application state management, cache, etc. While powerful, classic ASP applications became a challenge to manage as they grew in size and complexity. This was largely due to the lack of structure found in scripting environments coupled with the duplication of code resulting from the interleaving of code and markup. In order to capitalize on the strengths of classic ASP while addressing some of its challenges, ASP.NET took advantage of the code organization provided by the object-oriented languages of the .NET Framework while also preserving the server-side programming model to which classic ASP developers had grown accustomed.

The second group of target customers for ASP.NET was Windows business application developers. Unlike classic ASP developers, who were accustomed to writing HTML markup and the code to generate more HTML markup, WinForms developers (like the VB6 developers before them) were accustomed to a design time experience that included a canvas and a rich set of user interface controls. The first version of ASP.NET – also known as "Web Forms" provided a similar design time experience along with a server-side event model for user interface components and a set of infrastructure features (such as ViewState) to create a seamless developer experience between client and server side programming. Web Forms effectively hid the Web's stateless nature under a stateful event model that was familiar to WinForms developers.

Challenges Raised by the Historical Model

The net result was a mature, feature-rich runtime and developer programming model. However, with that feature-richness came a couple notable challenges. Firstly, the framework was **monolithic**, with logically disparate units of functionality being tightly coupled in the same System.Web.dll assembly (for example, the core HTTP objects with the Web forms framework). Secondly, ASP.NET was included as a part of the larger .NET Framework, which meant that the **time between releases was on the order of years.** This made it difficult for ASP.NET to keep pace with all of the changes happening in rapidly evolving Web development. Finally, System.Web.dll itself was coupled in a few different ways to a specific Web hosting option: Internet Information Services (IIS).

Evolutionary steps: ASP.NET MVC and ASP.NET Web API

And lots of change was happening in Web development! Web applications were increasingly being developed as a series of small, focused components rather than large frameworks. The number of components as well as the frequency with which they were released was increasing at an ever faster rate. It was clear that keeping pace with the Web would require frameworks to get smaller, decoupled and more focused rather than larger and more feature-rich, therefore the **ASP.NET team took several evolutionary steps to enable ASP.NET as a family of pluggable Web components rather than a single framework**.

One of the early changes was the rise in popularity of the well-known model-view-controller (MVC) design pattern thanks to Web development frameworks like Ruby on Rails. This style of building Web applications gave the developer greater control over her application's markup while still preserving the separation of markup and business logic, which was one of the initial selling points for ASP.NET. To meet the demand for this style of Web application development, Microsoft took the opportunity to position itself better for the future by **developing ASP.NET MVC out of band** (and not including it in the .NET Framework). ASP.NET MVC was released as an independent download. This gave the engineering team the flexibility to deliver updates much more frequently than had been previously possible.

Another major shift in Web application development was the shift from dynamic, server-generated Web pages to static initial markup with dynamic sections of the page generated from client-side script communicating **with backend Web APIs through AJAX requests**. This architectural shift helped propel the rise of Web APIs, and the development of the ASP.NET Web API framework. As in the case of ASP.NET MVC, the release of ASP.NET Web API provided another opportunity to evolve ASP.NET further as a more modular framework. The engineering team took advantage of the opportunity and **built ASP.NET Web API such that it had no dependencies on any of the core framework types found in System.Web.dll**. This enabled two things: first, it meant that ASP.NET Web API could evolve in a completely self-contained manner (and it could continue to iterate quickly because it is delivered via NuGet). Second, because there were no external dependencies to System.Web.dll, and therefore, no dependencies to IIS, ASP.NET Web API included the capability to run in a custom host (for example, a console application, Windows service, etc.)

The Future: A Nimble Framework

By decoupling framework components from one another and then releasing them on NuGet, frameworks could now **iterate more independently and more quickly**. Additionally, the power and flexibility of Web API's self-hosting capability proved very attractive to developers who wanted a **small, lightweight host** for their services. It proved so attractive, in fact, that other frameworks also wanted this capability, and this surfaced a new challenge in that each framework ran in its own host process on its own base address and needed to be managed (started, stopped, etc.) independently. A modern Web application generally supports static file serving, dynamic page generation, Web API, and more recently real-time/push notifications. Expecting that each of these services should be run and managed independently was simply not realistic.

What was needed was a single hosting abstraction that would enable a developer to compose an application from a variety of different components and frameworks, and then run that application on a supporting host.

The Open Web Interface for .NET (OWIN)

Inspired by the benefits achieved by Rack in the Ruby community, several members of the .NET community set out to create an abstraction between Web servers and framework components. Two design goals for the OWIN abstraction were that it was simple and that it took the fewest possible dependencies on other framework types. These two goals help ensure:

- New components could be more easily developed and consumed.
- Applications could be more easily ported between hosts and potentially entire platforms/operating systems.

The resulting abstraction consists of two core elements. The first is the environment dictionary. This data structure is responsible for storing all of the state necessary for processing an HTTP request and response, as well as any relevant server state. The environment dictionary is defined as follows:

```
IDictionary<string, object>
```

An OWIN-compatible Web server is responsible for populating the environment dictionary with data such as the body streams and header collections for an HTTP request and response. It is then the responsibility of the application or framework components to populate or update the dictionary with additional values and write to the response body stream.

In addition to specifying the type for the environment dictionary, the OWIN specification defines a list of core dictionary key value pairs. For example, the following table shows the required dictionary keys for an HTTP request:

KEY NAME	VALUE DESCRIPTION
`"owin.RequestBody"`	A Stream with the request body, if any. Stream.Null MAY be used as a placeholder if there is no request body. See Request Body.
`"owin.RequestHeaders"`	An `IDictionary<string, string[]>` of request headers. See Headers.
`"owin.RequestMethod"`	A `string` containing the HTTP request method of the request (e.g., `"GET"`, `"POST"`).
`"owin.RequestPath"`	A `string` containing the request path. The path MUST be relative to the "root" of the application delegate; see Paths.
`"owin.RequestPathBase"`	A `string` containing the portion of the request path corresponding to the "root" of the application delegate; see Paths.
`"owin.RequestProtocol"`	A `string` containing the protocol name and version (e.g. `"HTTP/1.0"` or `"HTTP/1.1"`).
`"owin.RequestQueryString"`	A `string` containing the query string component of the HTTP request URI, without the leading "?" (e.g., `"foo=bar&baz=quux"`). The value may be an empty string.
`"owin.RequestScheme"`	A `string` containing the URI scheme used for the request (e.g., `"http"`, `"https"`); see URI Scheme.

The second key element of OWIN is the application delegate. This is a function signature which serves as the primary interface between all components in an OWIN application. The definition for the application delegate is as follows:

```
Func<IDictionary<string, object>, Task>;
```

The application delegate then is simply an implementation of the Func delegate type where the function accepts the environment dictionary as input and returns a Task. This design has several implications for developers:

- There are a very small number of type dependencies required in order to write OWIN components. This greatly increases the accessibility of OWIN to developers.
- The asynchronous design enables the abstraction to be efficient with its handling of computing resources, particularly in more I/O intensive operations.
- Because the application delegate is an atomic unit of execution and because the environment dictionary is

carried as a parameter on the delegate, OWIN components can be easily chained together to create complex HTTP processing pipelines.

From an implementation perspective, OWIN is a specification (http://owin.org/html/owin.html). Its goal is not to be the next Web framework, but rather a specification for how Web frameworks and Web servers interact.

If you've investigated OWIN or Katana, you may also have noticed the Owin NuGet package and Owin.dll. This library contains a single interface, IAppBuilder, which formalizes and codifies the startup sequence described in section 4 of the OWIN specification. While not required in order to build OWIN servers, the IAppBuilder interface provides a concrete reference point, and it is used by the Katana project components.

Project Katana

Whereas both the OWIN specification and *Owin.dll* are community owned and community run open source efforts, the Katana project represents the set of OWIN components that, while still open source, are built and released by Microsoft. These components include both infrastructure components, such as hosts and servers, as well as functional components, such as authentication components and bindings to frameworks such as SignalR and ASP.NET Web API. The project has the following three high level goals:

- **Portable** – Components should be able to be easily substituted for new components as they become available. This includes all types of components, from the framework to the server and host. The implication of this goal is that third party frameworks can seamlessly run on Microsoft servers while Microsoft frameworks can potentially run on third party servers and hosts.
- **Modular/flexible**– Unlike many frameworks which include a myriad of features that are turned on by default, Katana project components should be small and focused, giving control over to the application developer in determining which components to use in her application.
- **Lightweight/performant/scalable** – By breaking the traditional notion of a framework into a set of small, focused components which are added explicitly by the application developer, a resulting Katana application can consume fewer computing resources, and as a result, handle more load, than with other types of servers and frameworks. As the requirements of the application demand more features from the underlying infrastructure, those can be added to the OWIN pipeline, but that should be an explicit decision on the part of the application developer. Additionally, the substitutability of lower level components means that as they become available, new high performance servers can seamlessly be introduced to improve the performance of OWIN applications without breaking those applications.

Getting Started with Katana Components

When it was first introduced, one aspect of the Node.js framework that immediately drew people's attention was the simplicity with which one could author and run a Web server. If Katana goals were framed in light of Node.js, one might summarize them by saying that Katana brings many of the benefits of Node.js (and frameworks like it) without forcing the developer to throw out everything she knows about developing ASP.NET Web applications. For this statement to hold true, getting started with the Katana project should be equally simple in nature to Node.js.

Creating "Hello World!"

One notable difference between JavaScript and .NET development is the presence (or absence) of a compiler. As such, the starting point for a simple Katana server is a Visual Studio project. However, we can start with the most minimal of project types: the Empty ASP.NET Web Application.

Next, we will install the Microsoft.Owin.Host.SystemWeb NuGet package into the project. This package provides an OWIN server that runs in the ASP.NET request pipeline. It can be found on the NuGet gallery and can be installed using either the Visual Studio package manager dialog or the package manager console with the following command:

```
install-package Microsoft.Owin.Host.SystemWeb
```

Installing the `Microsoft.Owin.Host.SystemWeb` package will install a few additional packages as dependencies. One of those dependencies is `Microsoft.Owin`, a library which provides several helper types and methods for developing OWIN applications. We can use those types to quickly write the following "hello world" server.

```
public class Startup
{
   public void Configuration(IAppBuilder app)
   {
      app.Run(context =>
      {
         context.Response.ContentType = "text/plain";
         return context.Response.WriteAsync("Hello World!");
      });
   }
}
```

This very simple Web server can now be run using Visual Studio's **F5** command and includes full support for debugging.

Switching hosts

By default, the previous "hello world" example runs in the ASP.NET request pipeline, which uses System.Web in the context of IIS. This can by itself add tremendous value as it enables us to benefit from the flexibility and composability of an OWIN pipeline with the management capabilities and overall maturity of IIS. However, there may be cases where the benefits provided by IIS are not required and the desire is for a smaller, more lightweight host. What is needed, then, to run our simple Web server outside of IIS and System.Web?

To illustrate the portability goal, moving from a Web-server host to a command line host requires simply adding the new server and host dependencies to project's output folder and then starting the host. In this example, we'll host our Web server in a Katana host called `OwinHost.exe` and will use the Katana HttpListener-based server.

Similarly to the other Katana components, these will be acquired from NuGet using the following command:

```
install-package OwinHost
```

From the command line, we can then navigate to the project root folder and simply run the `OwinHost.exe` (which was installed in the tools folder of its respective NuGet package). By default, `OwinHost.exe` is configured to look for the HttpListener-based server and so no additional configuration is needed. Navigating in a Web browser to `http://localhost:5000/` shows the application now running through the console.

Katana Architecture

The Katana component architecture divides an application into four logical layers, as depicted below: *host, server, middleware,* and *application*. The component architecture is factored in such a way that implementations of these layers can be easily substituted, in many cases, without requiring recompilation of the application.

Host

The host is responsible for:

- Managing the underlying process.

- Orchestrating the workflow that results in the selection of a server and the construction of an OWIN pipeline through which requests will be handled.

  At present, there are 3 primary hosting options for Katana-based applications:

IIS/ASP.NET: Using the standard HttpModule and HttpHandler types, OWIN pipelines can run on IIS as a part of an ASP.NET request flow. ASP.NET hosting support is enabled by installing the Microsoft.AspNet.Host.SystemWeb NuGet package into a Web application project. Additionally, because IIS acts as both a host and a server, the OWIN server/host distinction is conflated in this NuGet package, meaning that if using the SystemWeb host, a developer cannot substitute an alternate server implementation.

Custom Host: The Katana component suite gives a developer the ability to host applications in her own custom process, whether that is a console application, Windows service, etc. This capability looks similar to the self-host capability provided by Web API. The following example shows a custom host of Web API code:

```
static void Main()
{
    var baseAddress = new Uri("http://localhost:5000");

    var config = new HttpSelfHostConfiguration(baseAddress);
    config.Routes.MapHttpRoute("default", "{controller}");

    using (var svr = new HttpSelfHostServer(config))
    {
        svr.OpenAsync().Wait();
        Console.WriteLine("Press Enter to quit.");
        Console.ReadLine();
    }
}
```

The self-host setup for a Katana application is similar:

```
static void Main(string[] args)
{
    const string baseUrl = "http://localhost:5000/";

    using (WebApplication.Start<Startup>(new StartOptions { Url = baseUrl }))
    {
        Console.WriteLine("Press Enter to quit.");
        Console.ReadKey();
    }
}
```

One notable difference between the Web API and Katana self-host examples is that the Web API configuration code is missing from the Katana self-host example. In order to enable both portability and composability, Katana separates the code that starts the server from the code that configures the request processing pipeline. The code that configures Web API, then is contained in the class Startup, which is additionally specified as the type parameter in WebApplication.Start.

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        var config = new HttpConfiguration();
        config.Routes.MapHttpRoute("default", "{controller}");
        app.UseWebApi(config);
    }
}
```

The startup class will be discussed in greater detail later in the article. However, the code required to start a Katana self-host process looks strikingly similar to the code that you may be using today in ASP.NET Web API self-host applications.

OwinHost.exe: While some will want to write a custom process to run Katana Web applications, many would prefer to simply launch a pre-built executable that can start a server and run their application. For this scenario, the Katana component suite includes `OwinHost.exe`. When run from within a project's root directory, this executable will start a server (it uses the HttpListener server by default) and use conventions to find and run the user's startup class. For more granular control, the executable provides a number of additional command line parameters.

Server

While the host is responsible for starting and maintaining process within which the application runs, the responsibility of the server is to open a network socket, listen for requests, and send them through the pipeline of OWIN components specified by the user (as you may have already noticed, this pipeline is specified in the application developer's Startup class). Currently, the Katana project includes two server implementations:

- **Microsoft.Owin.Host.SystemWeb**: As previously mentioned, IIS in concert with the ASP.NET pipeline acts as both a host and a server. Therefore, when choosing this hosting option, IIS both manages host-level concerns such as process activation and listens for HTTP requests. For ASP.NET Web applications, it then sends the requests into the ASP.NET pipeline. The Katana SystemWeb host registers an ASP.NET HttpModule and HttpHandler to intercept requests as they flow through the HTTP pipeline and send them through the user-specified OWIN pipeline.
- **Microsoft.Owin.Host.HttpListener**: As its name indicates, this Katana server uses the .NET Framework's HttpListener class to open a socket and send requests into a developer-specified OWIN pipeline. This is currently the default server selection for both the Katana self-host API and OwinHost.exe.

Middleware/framework

As previously mentioned, when the server accepts a request from a client, it is responsible for passing it through a pipeline of OWIN components, which are specified by the developer's startup code. These pipeline

components are known as middleware.
At a very basic level, an OWIN middleware component simply needs to implement the OWIN application delegate so that it is callable.

```
Func<IDictionary<string, object>, Task>
```

However, in order to simplify the development and composition of middleware components, Katana supports a handful of conventions and helper types for middleware components. The most common of these is the `OwinMiddleware` class. A custom middleware component built using this class would look similar to the following:

```
public class LoggerMiddleware : OwinMiddleware
{
    private readonly ILog _logger;

    public LoggerMiddleware(OwinMiddleware next, ILog logger) : base(next)
    {
        _logger = logger;
    }

    public override async Task Invoke(IOwinContext context)
    {
        _logger.LogInfo("Middleware begin");
        await this.Next.Invoke(context);
        _logger.LogInfo("Middleware end");
    }
}
```

This class derives from `OwinMiddleware`, implements a constructor that accepts an instance of the next middleware in the pipeline as one of its arguments, and then passes it to the base constructor. Additional arguments used to configure the middleware are also declared as constructor parameters after the next middleware parameter.

At runtime, the middleware is executed via the overridden `Invoke` method. This method takes a single argument of type `OwinContext`. This context object is provided by the `Microsoft.Owin` NuGet package described earlier and provides strongly-typed access to the request, response and environment dictionary, along with a few additional helper types.

The middleware class can be easily added to the OWIN pipeline in the application startup code as follows:

```
public class Startup
{
   public void Configuration(IAppBuilder app)
   {
      app.Use<LoggerMiddleware>(new TraceLogger());

   }
}
```

Because the Katana infrastructure simply builds up a pipeline of OWIN middleware components, and because the components simply need to support the application delegate to participate in the pipeline, middleware components can range in complexity from simple loggers to entire frameworks like ASP.NET, Web API, or SignalR. For example, adding ASP.NET Web API to the previous OWIN pipeline requires adding the following startup code:

```
public class Startup
{
   public void Configuration(IAppBuilder app)
   {
      app.Use<LoggerMiddleware>(new TraceLogger());

      var config = new HttpConfiguration();
      // configure Web API
      app.UseWebApi(config);

      // additional middleware registrations
   }
}
```

The Katana infrastructure will build the pipeline of middleware components based on the order in which they were added to the IAppBuilder object in the Configuration method. In our example, then, LoggerMiddleware can handle all requests that flow through the pipeline, regardless of how those requests are ultimately handled. This enables powerful scenarios where a middleware component (e.g. an authentication component) can process requests for a pipeline that includes multiple components and frameworks (e.g. ASP.NET Web API, SignalR, and a static file server).

Applications

As illustrated by the previous examples, OWIN and the Katana project should not be thought of as a new application programming model, but rather as an abstraction to decouple application programming models and frameworks from server and hosting infrastructure. For example, when building Web API applications, the developer framework will continue to use the ASP.NET Web API framework, irrespective of whether or not the application runs in an OWIN pipeline using components from the Katana project. The one place where OWIN-related code will be visible to the application developer will be the application startup code, where the developer composes the OWIN pipeline. In the startup code, the developer will register a series of UseXx statements, generally one for each middleware component that will process incoming requests. This experience will have the same effect as registering HTTP modules in the current System.Web world. Typically, a larger framework middleware, such as ASP.NET Web API or SignalR will be registered at the end of the pipeline. Cross-cutting middleware components, such as those for authentication or caching, are generally registered towards the beginning of the pipeline so that they will process requests for all of the frameworks and components registered later in the pipeline. This separation of the middleware components from each other and from the underlying infrastructure components enables the components to evolve at different velocities while ensuring that the overall system remains stable.

Components – NuGet Packages

Like many current libraries and frameworks, the Katana project components are delivered as a set of NuGet packages. For the upcoming version 2.0, the Katana package dependency graph looks as follows. (Click on image for larger view.)

Nearly every package in the Katana project depends, directly or indirectly, on the Owin package. You may remember that this is the package that contains the IAppBuilder interface, which provides a concrete implementation of the application startup sequence described in section 4 of the OWIN specification. Additionally, many of the packages depend on Microsoft.Owin, which provides a set of helper types for working with HTTP requests and responses. The remainder of the package can be classified as either hosting infrastructure packages (servers or hosts) or middleware. Packages and dependencies that are external to the Katana project are displayed in orange.

The hosting infrastructure for Katana 2.0 includes both the SystemWeb and HttpListener-based servers, the OwinHost package for running OWIN applications using OwinHost.exe, and the Microsoft.Owin.Hosting package for self-hosting OWIN applications in a custom host (e.g. console application, Windows service, etc.)

For Katana 2.0, the middleware components are primarily focused on providing different means of authentication. One additional middleware component for diagnostics is provided, which enables support for a start and error page. As OWIN grows into the de facto hosting abstraction, the ecosystem of middleware components, both those developed by Microsoft and third parties, will also grow in number.

Conclusion

From its beginning, the Katana project's goal has not been to create and thereby force developers to learn yet another Web framework. Rather, the goal has been to create an abstraction to give .NET Web application developers more choice than has previously been possible. By breaking up the logical layers of a typical Web application stack into a set of replaceable components, the Katana project enables components throughout the stack to improve at whatever rate makes sense for those components. By building all components around the simple OWIN abstraction, Katana enables frameworks and the applications built on top of them to be portable across a variety of different servers and hosts. By putting the developer in control of the stack, Katana ensures that the developer makes the ultimate choice about how lightweight or how feature-rich her Web stack should be.

Getting Started with OWIN and Katana

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

Open Web Interface for .NET (OWIN) defines an abstraction between .NET web servers and web applications. By decoupling the web server from the application, OWIN makes it easier to create middleware for .NET web development. Also, OWIN makes it easier to port web applications to other hosts—for example, self-hosting in a Windows service or other process.

OWIN is a community-owned specification, not an implementation. The Katana project is a set of open-source OWIN components developed by Microsoft. For a general overview of both OWIN and Katana, see An Overview of Project Katana. In this article, I will jump right into code to get started.

This tutorial uses Visual Studio 2013 Release Candidate, but you can also use Visual Studio 2012. A few of the steps are different in Visual Studio 2012, which I note below.

Host OWIN in IIS

In this section, we'll host OWIN in IIS. This option gives you the flexibility and composability of an OWIN pipeline together with the mature feature set of IIS. Using this option, the OWIN application runs in the ASP.NET request pipeline.

First, create a new ASP.NET Web Application project. (In Visual Studio 2012, use the ASP.NET Empty Web Application project type.)

In the **New ASP.NET Project** dialog, select the **Empty** template.

Add NuGet Packages

Next, add the required NuGet packages. From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, type the following command:

```
install-package Microsoft.Owin.Host.SystemWeb -Pre
```

Add a Startup Class

Next, add an OWIN startup class. In Solution Explorer, right-click the project and select **Add**, then select **New Item**. In the **Add New Item** dialog, select **Owin Startup class**. For more info on configuring the startup class, see OWIN Startup Class Detection.

Add the following code to the `Startup1.Configuration` method:

```
public void Configuration(IAppBuilder app)
{
    // New code:
    app.Run(context =>
    {
        context.Response.ContentType = "text/plain";
        return context.Response.WriteAsync("Hello, world.");
    });
}
```

This code adds a simple piece of middleware to the OWIN pipeline, implemented as a function that receives a **Microsoft.Owin.IOwinContext** instance. When the server receives an HTTP request, the OWIN pipeline invokes the middleware. The middleware sets the content type for the response and writes the response body.

> **NOTE**
>
> The OWIN Startup class template is available in Visual Studio 2013. If you are using Visual Studio 2012, just add a new empty class named `Startup1`, and paste in the following code:

```
using System;
using System.Threading.Tasks;
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(OwinApp.Startup1))]

namespace OwinApp
{
    public class Startup1
    {
        public void Configuration(IAppBuilder app)
        {
          app.Run(context =>
          {
              context.Response.ContentType = "text/plain";
              return context.Response.WriteAsync("Hello, world.");
          });
        }
    }
}
```

Run the Application

Press F5 to begin debugging. Visual Studio will open a browser window to `http://localhost:*port*/`. The page should look like the following:

Self-Host OWIN in a Console Application

It's easy to convert this application from IIS hosting to self-hosting in a custom process. With IIS hosting, IIS acts as both the HTTP server and as the process that hosts the service. With self-hosting, your application creates the process and uses the **HttpListener** class as the HTTP server.

In Visual Studio, create a new console application. In the Package Manager Console window, type the following command:

```
Install-Package Microsoft.Owin.SelfHost -Pre
```

Add a `Startup1` class from part 1 of this tutorial to the project. You don't need to modify this class.

Implement the application's `Main` method as follows.

```
class Program
{
    static void Main(string[] args)
    {
        using (Microsoft.Owin.Hosting.WebApp.Start<Startup1>("http://localhost:9000"))
        {
            Console.WriteLine("Press [enter] to quit...");
            Console.ReadLine();
        }
    }
}
```

When you run the console application, the server starts listening to `http://localhost:9000`. If you navigate to this

address in a web browser, you will see the "Hello world" page.

Add OWIN Diagnostics

The Microsoft.Owin.Diagnostics package contains middleware that catches unhandled exceptions and displays an HTML page with error details. This page functions much like the ASP.NET error page that is sometimes called the "yellow screen of death" (YSOD). Like the YSOD, the Katana error page is useful during development, but it's a good practice to disable it in production mode.

To install the Diagnostics package in your project, type the following command in the Package Manager Console window:

```
install-package Microsoft.Owin.Diagnostics -Pre
```

Change the code in your `Startup1.Configuration` method as follows:

```
public void Configuration(IAppBuilder app)
{
    // New code: Add the error page middleware to the pipeline.
    app.UseErrorPage();

    app.Run(context =>
    {
        // New code: Throw an exception for this URI path.
        if (context.Request.Path.Equals(new PathString("/fail")))
        {
            throw new Exception("Random exception");
        }

        context.Response.ContentType = "text/plain";
        return context.Response.WriteAsync("Hello, world.");
    });
}
```

Now use CTRL+F5 to run the application without debugging, so that Visual Studio will not break on the exception. The application behaves the same as before, until you navigate to `http://localhost/fail`, at which point the application throws the exception. The error page middleware will catch the exception and display an HTML page with information about the error. You can click the tabs to see the stack, query string, cookies, request header, and OWIN environment variables.

Next Steps

- OWIN Startup Class Detection
- Use OWIN to Self-Host ASP.NET Web API
- Use OWIN to Self-Host SignalR

SameSite cookies and the Open Web Interface for .NET (OWIN)

2/20/2020 • 6 minutes to read • Edit Online

By Rick Anderson

`SameSite` is an IETF draft designed to provide some protection against cross-site request forgery (CSRF) attacks. The SameSite 2019 draft:

- Treats cookies as `SameSite=Lax` by default.
- States cookies that explicitly assert `SameSite=None` in order to enable cross-site delivery should be marked as `Secure`.

`Lax` works for most app cookies. Some forms of authentication like OpenID Connect (OIDC) and WS-Federation default to POST based redirects. The POST based redirects trigger the `SameSite` browser protections, so `SameSite` is disabled for these components. Most OAuth logins aren't affected due to differences in how the request flows. All other components do **not** set `SameSite` by default and use the clients default behavior (old or new).

The `None` parameter causes compatibility problems with clients that implemented the prior 2016 draft standard (for example, iOS 12). See Supporting older browsers in this document.

Each OWIN component that emits cookies needs to decide if `SameSite` is appropriate.

For the ASP.NET 4.x version of this article, see Work with SameSite cookies in ASP.NET.

API usage with SameSite

`Microsoft.Owin` has its own `SameSite` implementation:

- That is not directly dependent on the one in `System.Web`.
- `SameSite` works on all versions targetable by the `Microsoft.Owin` packages, .NET 4.5 and later.
- Only the SystemWebCookieManager component directly interacts with the `System.Web` `HttpCookie` class.

`SystemWebCookieManager` depends on the .NET 4.7.2 `System.Web` APIs to enable `SameSite` support, and the patches to change the behavior.

The reasons to use `SystemWebCookieManager` are outlined in OWIN and System.Web response cookie integration issues. `SystemWebCookieManager` is recommended when running on `System.Web`.

The following code sets `SameSite` to `Lax`:

```
owinContext.Response.Cookies.Append("My Key", "My Value", new CookieOptions()
{
    SameSite = SameSiteMode.Lax
});
```

The following APIs use `SameSite`:

- Microsoft.Owin.SameSiteMode
- CookieOptions.SameSite
- CookieAuthenticationOptions Class

- CookieAuthenticationOptions.CookieSameSite
- ICookieManager
- SystemWebCookieManager
- SystemWebChunkingCookieManager
- CookieAuthenticationOptions.CookieManager
- OpenIdConnectAuthenticationOptions.CookieManager

History and changes

Microsoft.Owin never supported the `SameSite` 2016 draft standard.

Support for the SameSite 2019 draft is only available in `Microsoft.Owin` 4.1.0 and later. There are no patches for prior versions.

The 2019 draft of the `SameSite` specification:

- Is **not** backwards compatible with the 2016 draft. For more information, see Supporting older browsers in this document.
- Specifies cookies are treated as `SameSite=Lax` by default.
- Specifies cookies that explicitly assert `SameSite=None` in order to enable cross-site delivery should be marked as `Secure`. `None` is a new entry to opt out.
- Is scheduled to be enabled by Chrome by default in Feb 2020. Browsers started moving to this standard in 2019.
- Is supported by patches issued as described in KB articles. For more information, see KB articles that support SameSite in .NET Framework.

Supporting older browsers

The 2016 `SameSite` standard mandated that unknown values must be treated as `SameSite=Strict` values. Apps accessed from older browsers which support the 2016 `SameSite` standard may break when they get a `SameSite` property with a value of `None`. Web apps must implement browser detection if they intend to support older browsers. ASP.NET doesn't implement browser detection because User-Agents values are highly volatile and change frequently. An extension point in ICookieManager allows plugging in User-Agent specific logic.

In `Startup.Configuration`, add code similar to the following:

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        app.UseOpenIdConnectAuthentication(
             new OpenIdConnectAuthenticationOptions
             {
                 // … Your preexisting options …
                 CookieManager = new SameSiteCookieManager(
                                     new SystemWebCookieManager())
             });

        // Remaining code removed for brevity.
```

The preceding code requires the .NET 4.7.2 or later `SameSite` patch.

The following code shows an example implementation of `SameSiteCookieManager`:

```
public class SameSiteCookieManager : ICookieManager
{
    private readonly ICookieManager _innerManager;

    public SameSiteCookieManager() : this(new CookieManager())
    {
    }

    public SameSiteCookieManager(ICookieManager innerManager)
    {
        _innerManager = innerManager;
    }

    public void AppendResponseCookie(IOwinContext context, string key, string value,
                                     CookieOptions options)
    {
        CheckSameSite(context, options);
        _innerManager.AppendResponseCookie(context, key, value, options);
    }

    public void DeleteCookie(IOwinContext context, string key, CookieOptions options)
    {
        CheckSameSite(context, options);
        _innerManager.DeleteCookie(context, key, options);
    }

    public string GetRequestCookie(IOwinContext context, string key)
    {
        return _innerManager.GetRequestCookie(context, key);
    }

    private void CheckSameSite(IOwinContext context, CookieOptions options)
    {
        if (options.SameSite == Microsoft.Owin.SameSiteMode.None
                            && DisallowsSameSiteNone(context))
        {
            options.SameSite = null;
        }
    }
```

In the preceding sample, `DisallowsSameSiteNone` is called in the `CheckSameSite` method. `DisallowsSameSiteNone` is a user method that detects if the user agent doesn't support `SameSite` `None`:

```
private void CheckSameSite(IOwinContext context, CookieOptions options)
{
    if (options.SameSite == Microsoft.Owin.SameSiteMode.None
                        && DisallowsSameSiteNone(context))
    {
        options.SameSite = null;
    }
}
```

The following code shows a sample `DisallowsSameSiteNone` method:

WARNING

The following code is for demonstration only:

- It should not be considered complete.
- It is not maintained or supported.

```
public static bool DisallowsSameSiteNone(IOwinContext context)
{
    var userAgent = context.Request.Headers["User-Agent"];

    if (string.IsNullOrEmpty(userAgent))
    {
        return false;
    }

    // Cover all iOS based browsers here. This includes:
    // - Safari on iOS 12 for iPhone, iPod Touch, iPad
    // - WkWebview on iOS 12 for iPhone, iPod Touch, iPad
    // - Chrome on iOS 12 for iPhone, iPod Touch, iPad
    // All of which are broken by SameSite=None, because they use the iOS
    // networking stack.
    if (userAgent.Contains("CPU iPhone OS 12") ||
        userAgent.Contains("iPad; CPU OS 12"))
    {
        return true;
    }

    // Cover Mac OS X based browsers that use the Mac OS networking stack.
    // This includes:
    // - Safari on Mac OS X.
    // This does not include:
    // - Chrome on Mac OS X
    // Because they do not use the Mac OS networking stack.
    if (userAgent.Contains("Macintosh; Intel Mac OS X 10_14") &&
        userAgent.Contains("Version/") && userAgent.Contains("Safari"))
    {
        return true;
    }

    // Cover Chrome 50-69, because some versions are broken by SameSite=None,
    // and none in this range require it.
    // Note: this covers some pre-Chromium Edge versions,
    // but pre-Chromium Edge does not require SameSite=None.
    if (userAgent.Contains("Chrome/5") || userAgent.Contains("Chrome/6"))
    {
        return true;
    }

    return false;
}
```

Test apps for SameSite problems

Apps that interact with remote sites such as through third-party login need to:

- Test the interaction on multiple browsers.
- Apply the browser detection and mitigation discussed in this document.

Test web apps using a client version that can opt-in to the new `SameSite` behavior. Chrome, Firefox, and Chromium Edge all have new opt-in feature flags that can be used for testing. After your app applies the `SameSite` patches, test it with older client versions, especially Safari. For more information, see Supporting older browsers in this document.

Test with Chrome

Chrome 78+ gives misleading results because it has a temporary mitigation in place. The Chrome 78+ temporary mitigation allows cookies less than two minutes old. Chrome 76 or 77 with the appropriate test flags enabled provides more accurate results. To test the new `SameSite` behavior toggle `chrome://flags/#same-site-by-default-cookies` to **Enabled**. Older versions of Chrome (75 and below) are reported

to fail with the new `None` setting. See Supporting older browsers in this document.

Google does not make older chrome versions available. Follow the instructions at Download Chromium to test older versions of Chrome. Do **not** download Chrome from links provided by searching for older versions of chrome.

- Chromium 76 Win64
- Chromium 74 Win64

Test with Safari

Safari 12 strictly implemented the prior draft and fails when the new `None` value is in a cookie. `None` is avoided via the browser detection code Supporting older browsers in this document. Test Safari 12, Safari 13, and WebKit based OS style logins using MSAL, ADAL or whatever library you are using. The problem is dependent on the underlying OS version. OSX Mojave (10.14) and iOS 12 are known to have compatibility problems with the new `SameSite` behavior. Upgrading the OS to OSX Catalina (10.15) or iOS 13 fixes the problem. Safari does not currently have an opt-in flag for testing the new spec behavior.

Test with Firefox

Firefox support for the new standard can be tested on version 68+ by opting in on the `about:config` page with the feature flag `network.cookie.sameSite.laxByDefault`. There haven't been reports of compatibility issues with older versions of Firefox.

Test with Edge browser

Edge supports the old `SameSite` standard. Edge version 44 doesn't have any known compatibility problems with the new standard.

Test with Edge (Chromium)

`SameSite` flags are set on the `edge://flags/#same-site-by-default-cookies` page. No compatibility issues were discovered with Edge Chromium.

Test with Electron

Versions of Electron include older versions of Chromium. For example, the version of Electron used by Teams is Chromium 66, which exhibits the older behavior. You must perform your own compatibility testing with the version of Electron your product uses. See Supporting older browsers in the following section.

by Microsoft

Katana Samples

ASP.NET Routes Sample | Source Code
In some applications you will want to hook up OWIN components in the Asp.Net route table side by side with non-OWIN components. This sample shows how to use the RouteCollection extension methods MapOwinPath and MapOwinRoute provided by Microsoft.Owin.Host.SystemWeb.

Branching Pipelines Sample | Source Code
OWIN request processing pipelines do not need to be linear, they can be branched to process requests in different ways. This sample shows how to construct a branching pipeline based on request paths or other request data such as headers. These components are available in the Microsoft.Owin.Mapping nuget package.

Custom Server Sample | Source Code
Shows how to use a custom OWIN server when self-hosting OWIN.

Embedded Sample | Source Code
Some OWIN servers can be run inside of your own process ("self-hosted"). This sample shows how to start an OWIN application using the tools provided by the Microsoft.Owin.Hosting nuget package.

HelloWorld Sample | Source Code
OWIN is a HTTP server API abstraction that enables application portability across various servers. This sample demonstrates how to write a Hello World application using some **simple wrappers** around the raw OWIN abstraction and run it on a web server like ASP.NET.

Hello World Raw OWIN Sample | Source Code
This sample demonstrates how to write a Hello World application using the **raw** OWIN abstraction and run it on a web server like Asp.Net.

SignalR Sample | Source Code
Shows how to self-host SignalR using OWIN / Katana. For more info about self-hosting SignalR, see Tutorial: SignalR Self-Host.

Static Files Sample | Source Code
Shows how to support HTTP requests for static files using OWIN / Katana.

Web API | Source Code
This sample shows how to host OWIN in IIS and add Web API to the OWIN pipeline.

Web Socket Sample | Source Code
Shows how to support Web Sockets in OWIN by using the System.Net.WebSockets.WebSocket class.

OWIN Startup Class Detection

2/20/2020 • 6 minutes to read • Edit Online

This tutorial shows how to configure which OWIN startup class is loaded. For more information on OWIN, see An Overview of Project Katana. This tutorial was written by Rick Anderson (@RickAndMSFT), Praburaj Thiagarajan, and Howard Dierking (@howard_dierking).

Prerequisites

Visual Studio 2017

OWIN Startup Class Detection

Every OWIN Application has a startup class where you specify components for the application pipeline. There are different ways you can connect your startup class with the runtime, depending on the hosting model you choose (OwinHost, IIS, and IIS-Express). The startup class shown in this tutorial can be used in every hosting application. You connect the startup class with the hosting runtime using one of the these approaches:

1. **Naming Convention**: Katana looks for a class named `Startup` in namespace matching the assembly name or the global namespace.

2. **OwinStartup Attribute**: This is the approach most developers will take to specify the startup class. The following attribute will set the startup class to the `TestStartup` class in the `StartupDemo` namespace.

   ```
   [assembly: OwinStartup(typeof(StartupDemo.TestStartup))]
   ```

   The `OwinStartup` attribute overrides the naming convention. You can also specify a friendly name with this attribute, however, using a friendly name requires you to also use the `appSetting` element in the configuration file.

3. **The appSetting element in the Configuration file**: The `appSetting` element overrides the `OwinStartup` attribute and naming convention. You can have multiple startup classes (each using an `OwinStartup` attribute) and configure which startup class will be loaded in a configuration file using markup similar to the following:

   ```
   <appSettings>
     <add key="owin:appStartup" value="StartupDemo.ProductionStartup" />
   </appSettings>
   ```

   The following key, which explicitly specifies the startup class and assembly can also be used:

   ```
   <add key="owin:appStartup" value="StartupDemo.ProductionStartup, StartupDemo" />
   ```

   The following XML in the configuration file specifies a friendly startup class name of `ProductionConfiguration`.

```
<appSettings>
  <add key="owin:appStartup" value="ProductionConfiguration" />
</appSettings>
```

The above markup must be used with the following `OwinStartup` attribute which specifies a friendly name and causes the `ProductionStartup2` class to run.

```
[assembly: OwinStartup("ProductionConfiguration", typeof(StartupDemo.ProductionStartup2))]

namespace StartupDemo
{
    public class ProductionStartup
    {
        public void Configuration(IAppBuilder app)
        {
            app.Run(context =>
            {
                string t = DateTime.Now.Millisecond.ToString();
                return context.Response.WriteAsync(t + " Production OWIN App");
            });
        }
    }
    public class ProductionStartup2
    {
        public void Configuration(IAppBuilder app)
        {
            app.Run(context =>
            {
                string t = DateTime.Now.Millisecond.ToString();
                return context.Response.WriteAsync(t + " 2nd Production OWIN App");
            });
        }
    }
}
```

4. To disable OWIN startup discovery add the `appSetting owin:AutomaticAppStartup` with a value of `"false"` in the web.config file.

```
<add key="owin:AutomaticAppStartup" value="false" />
```

Create an ASP.NET Web App using OWIN Startup

1. Create an empty Asp.Net web application and name it **StartupDemo**. - Install `Microsoft.Owin.Host.SystemWeb` using the NuGet package manager. From the **Tools** menu, select **NuGet Package Manager**, and then **Package Manager Console**. Enter the following command:

```
Install-Package Microsoft.Owin.Host.SystemWeb
```

2. Add an OWIN startup class. In Visual Studio 2017 right-click the project and select **Add Class**.- In the **Add New Item** dialog box, enter *OWIN* in the search field, and change the name to Startup.cs, and then select **Add**.

The next time you want to add an *Owin Startup class*, it will be in available from the **Add** menu.

Alternatively, you can right-click the project and select **Add**, then select **New Item**, and then select the **Owin Startup class**.

- Replace the generated code in the *Startup.cs* file with the following:

```
using System;
using System.Threading.Tasks;
using Microsoft.Owin;
using Owin;
using System.IO;

//[assembly: OwinStartup(typeof(StartupDemo.Startup))]

namespace StartupDemo
{
   public class Startup
   {
      public void Configuration(IAppBuilder app)
      {
         app.Use((context, next) =>
         {
            TextWriter output = context.Get<TextWriter>("host.TraceOutput");
            return next().ContinueWith(result =>
            {
               output.WriteLine("Scheme {0} : Method {1} : Path {2} : MS {3}",
               context.Request.Scheme, context.Request.Method, context.Request.Path, getTime());
            });
         });

         app.Run(async context =>
         {
            await context.Response.WriteAsync(getTime() + " My First OWIN App");
         });
      }

      string getTime()
      {
         return DateTime.Now.Millisecond.ToString();
      }
   }
}
```

The `app.Use` lambda expression is used to register the specified middleware component to the OWIN pipeline. In this case we are setting up logging of incoming requests before responding to the incoming request. The `next` parameter is the delegate (Func < Task >) to the next component in the pipeline. The `app.Run` lambda expression hooks up the pipeline to incoming requests and provides the response mechanism.

> **NOTE**
>
> In the code above we have commented out the `OwinStartup` attribute and we're relying on the convention of running the class named `Startup` .- Press ***F5*** to run the application. Hit refresh a few times.

Note: The number shown in the images in this tutorial will not match the number you see. The millisecond string is used to show a new response when you refresh the page. You can see the trace information in the **Output** window.

Add More Startup Classes

In this section we'll add another Startup class. You can add multiple OWIN startup class to your application. For example, you might want to create startup classes for development, testing and production.

1. Create a new OWIN Startup class and name it `ProductionStartup`.
2. Replace the generated code with the following:

```
using System;
using System.Threading.Tasks;
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(StartupDemo.ProductionStartup))]

namespace StartupDemo
{
    public class ProductionStartup
    {
        public void Configuration(IAppBuilder app)
        {
            app.Run(context =>
            {
                string t = DateTime.Now.Millisecond.ToString();
                return context.Response.WriteAsync(t + " Production OWIN App");
            });
        }
    }
}
```

3. Press Control F5 to run the app. The `OwinStartup` attribute specifies the production startup class is run.

4. Create another OWIN Startup class and name it `TestStartup`.

5. Replace the generated code with the following:

```
using System;
using System.Threading.Tasks;
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup("TestingConfiguration", typeof(StartupDemo.TestStartup))]

namespace StartupDemo
{
    public class TestStartup
    {
        public void Configuration(IAppBuilder app)
        {
            app.Run(context =>
            {
                string t = DateTime.Now.Millisecond.ToString();
                return context.Response.WriteAsync(t + " Test OWIN App");
            });
        }
    }
}
```

The `OwinStartup` attribute overload above specifies `TestingConfiguration` as the *friendly* name of the Startup class.

6. Open the *web.config* file and add the OWIN App startup key which specifies the friendly name of the Startup class:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <appSettings>
    <add key="owin:appStartup" value="TestingConfiguration" />
  </appSettings>
  <system.web>
    <compilation debug="true" targetFramework="4.5" />
    <httpRuntime targetFramework="4.5" />
  </system.web>
</configuration>
```

7. Press Control F5 to run the app. The app settings element takes precedent, and the test configuration is run.

8. Remove the *friendly* name from the `OwinStartup` attribute in the `TestStartup` class.

```
[assembly: OwinStartup(typeof(StartupDemo.TestStartup))]
```

9. Replace the OWIN App startup key in the *web.config* file with the following:

```
<add key="owin:appStartup" value="StartupDemo.TestStartup" />
```

10. Revert the `OwinStartup` attribute in each class to the default attribute code generated by Visual Studio:

```
[assembly: OwinStartup(typeof(StartupDemo.Startup))]
[assembly: OwinStartup(typeof(StartupDemo.ProductionStartup))]
[assembly: OwinStartup(typeof(StartupDemo.TestStartup))]
```

Each of the OWIN App startup keys below will cause the production class to run.

```
<add key="owin:appStartup" value="StartupDemo.ProductionStartup" />
<add key="owin:appStartup" value="StartupDemo.ProductionStartup, StartupDemo" />
<add key="owin:appStartup" value="StartupDemo.ProductionStartup.Configuration, StartupDemo" />
```

The last startup key specifies the startup configuration method. The following OWIN App startup key allows you to change the name of the configuration class to `MyConfiguration` .

```
<add key="owin:appStartup" value="StartupDemo.ProductionStartup2.MyConfiguration" />
```

Using Owinhost.exe

1. Replace the Web.config file with the following markup:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
   <appSettings>
      <add key="owin:appStartup" value="StartupDemo.Startup" />
      <add key="owin:appStartup" value="StartupDemo.TestStartup" />
   </appSettings>
  <system.web>
    <compilation debug="true" targetFramework="4.5" />
    <httpRuntime targetFramework="4.5" />
  </system.web>
</configuration>
```

   The last key wins, so in this case `TestStartup` is specified.

2. Install Owinhost from the PMC:

```
Install-Package OwinHost
```

3. Navigate to the application folder (the folder containing the *Web.config* file) and in a command prompt and type:

```
..\packages\Owinhost<Version>\tools\Owinhost.exe
```

   The command window will show:

```
C:\StartupDemo\StartupDemo>..\packages\OwinHost.2.0.0\tools\Owin
Host.exe
Starting with the default port: 5000 (http://localhost:5000/)
Started successfully
Press Enter to exit
```

4. Launch a browser with the URL `http://localhost:5000/`.

   OwinHost honored the startup conventions listed above.

5. In the command window, press Enter to exit OwinHost.

6. In the `ProductionStartup` class, add the following OwinStartup attribute which specifies a friendly name of *ProductionConfiguration*.

```
[assembly: OwinStartup("ProductionConfiguration",
           typeof(StartupDemo.ProductionStartup))]
```

7. In the command prompt and type:

```
..\packages\OwinHost.2.0.0\tools\OwinHost.exe ProductionConfiguration
```

The Production startup class is loaded. 
Our application has multiple startup classes, and in this example we have deferred which startup class to load until runtime.

8. Test the following runtime startup options:

```
..\packages\OwinHost.2.0.0-rc1\tools\OwinHost.exe StartupDemo.TestStartup
..\packages\OwinHost.2.0.0-rc1\tools\OwinHost.exe "StartupDemo.TestStartup,StartupDemo"
..\packages\OwinHost.2.0.0-rc1\tools\OwinHost.exe StartupDemo.TestStartup.Configuration
..\packages\OwinHost.2.0.0-rc1\tools\OwinHost.exe "StartupDemo.TestStartup.Configuration,StartupDemo"
```

Enabling Windows Authentication in Katana

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

This article shows how to enable Windows Authentication in Katana. It covers two scenarios: Using IIS to host Katana, and using HttpListener to self-host Katana in a custom process. Thanks to Barry Dorrans, David Matson, and Chris Ross for reviewing this article.

Katana is Microsoft's implementation of OWIN, the Open Web Interface for .NET. You can read an introduction to OWIN and Katana here. The OWIN architecture has several layers:

- Host: Manages the process in which the OWIN pipeline runs.
- Server: Opens a network socket and listens for requests.
- Middleware: Processes the HTTP request and response.

Katana currently provides two servers, both of which support Windows Integrated Authentication:

- **Microsoft.Owin.Host.SystemWeb**. Uses IIS with the ASP.NET pipeline.
- **Microsoft.Owin.Host.HttpListener**. Uses System.Net.HttpListener. This server is currently the default option when self-hosting Katana.

> **NOTE**
>
> Katana does not currently provide OWIN middleware for Windows Authentication, because this functionality is already available in the servers.

Windows Authentication in IIS

Using Microsoft.Owin.Host.SystemWeb, you can simply enable Windows Authentication in IIS.

Let's start by creating a new ASP.NET application, using the "ASP.NET Empty Web Application" project template.

Next, add NuGet packages. From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.Owin.Host.SystemWeb -pre
```

Now add a class named `Startup` with the following code:

```
using Owin;

namespace KatanaWebHost
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            app.Run(context =>
            {
                context.Response.ContentType = "text/plain";
                return context.Response.WriteAsync("Hello World!");
            });
        }
    }
}
```

That's all you need to create a "Hello world" application for OWIN, running on IIS. Press F5 to debug the application. You should see "Hello World!" in the browser window.

Next, we'll enable Windows Authentication in IIS Express. From the **View** menu, select **Properties**. Click on the project name in Solution Explorer to view the project properties.

In the **Properties** window, set **Anonymous Authentication** to **Disabled** and set **Windows Authentication** to **Enabled**.

When you run the application from Visual Studio, IIS Express will require the user's Windows credentials. You can see this by using Fiddler or another HTTP debugging tool. Here is an example HTTP response:

```
HTTP/1.1 401 Unauthorized
Cache-Control: private
Content-Type: text/html; charset=utf-8
Server: Microsoft-IIS/8.0
WWW-Authenticate: Negotiate
WWW-Authenticate: NTLM
X-Powered-By: ASP.NET
Date: Sun, 28 Jul 2013 07:28:51 GMT
Content-Length: 6062
Proxy-Support: Session-Based-Authentication
```

The WWW-Authenticate headers in this response indicate that the server supports the Negotiate protocol, which uses either Kerberos or NTLM.

Later, when you deploy the application to a server, follow these steps to enable Windows Authentication in IIS on that server.

Windows Authentication in HttpListener

If you are using Microsoft.Owin.Host.HttpListener to self-host Katana, you can enable Windows Authentication directly on the **HttpListener** instance.

First, create a new console application. Next, add NuGet packages. From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.Owin.SelfHost -Pre
```

Now add a class named `Startup` with the following code:

```
using Owin;
using System.Net;

namespace KatanaSelfHost
{
    class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            HttpListener listener =
                (HttpListener)app.Properties["System.Net.HttpListener"];
            listener.AuthenticationSchemes =
                AuthenticationSchemes.IntegratedWindowsAuthentication;

            app.Run(context =>
            {
                context.Response.ContentType = "text/plain";
                return context.Response.WriteAsync("Hello World!");
            });
        }
    }
}
```

This class implements the same "Hello world" example from before, but it also sets Windows Authentication as the authentication scheme.

Inside the `Main` function, start the OWIN pipeline:

```
using Microsoft.Owin.Hosting;
using System;

namespace KatanaSelfHost
{
    class Program
    {
        static void Main(string[] args)
        {
            using (WebApp.Start<Startup>("http://localhost:9000"))
            {
                Console.WriteLine("Press Enter to quit.");
                Console.ReadKey();
            }
        }
    }
}
```

You can send a request in Fiddler to confirm that the application is using Windows Authentication:

```
HTTP/1.1 401 Unauthorized
Content-Length: 0
Server: Microsoft-HTTPAPI/2.0
WWW-Authenticate: Negotiate
WWW-Authenticate: NTLM
Date: Sun, 28 Jul 2013 21:02:21 GMT
Proxy-Support: Session-Based-Authentication
```

OWIN Middleware in the IIS integrated pipeline

2/20/2020 • 5 minutes to read • Edit Online

by Praburaj Thiagarajan, Rick Anderson

> This article shows how to run OWIN middleware Components (OMCs) in the IIS integrated pipeline, and how to set the pipeline event an OMC runs on. You should review An Overview of Project Katana and OWIN Startup Class Detection before reading this tutorial. This tutorial was written by Rick Anderson (@RickAndMSFT), Chris Ross, Praburaj Thiagarajan, and Howard Dierking (@howard_dierking).

Although OWIN middleware components (OMCs) are primarily designed to run in a server-agnostic pipeline, it is possible to run an OMC in the IIS integrated pipeline as well (**classic mode is *not* supported**). An OMC can be made to work in the IIS integrated pipeline by installing the following package from the Package Manager Console (PMC):

```
Install-Package Microsoft.Owin.Host.SystemWeb
```

This means that all application frameworks, even those that are not yet able to run outside of IIS and System.Web, can benefit from existing OWIN middleware components.

> **NOTE**
>
> All of the `Microsoft.Owin.Security.*` packages shipping with the new Identity System in Visual Studio 2013 (for example: Cookies, Microsoft Account, Google, Facebook, Twitter, Bearer Token, OAuth, Authorization server, JWT, Azure Active directory, and Active directory federation services) are authored as OMCs, and can be used in both self-hosted and IIS-hosted scenarios.

How OWIN Middleware Executes in the IIS Integrated Pipeline

For OWIN console applications, the application pipeline built using the startup configuration is set by the order the components are added using the `IAppBuilder.Use` method. That is, the OWIN pipeline in the Katana runtime will process OMCs in the order they were registered using `IAppBuilder.Use`. In the IIS integrated pipeline the request pipeline consists of HttpModules subscribed to a pre-defined set of the pipeline events such as BeginRequest, AuthenticateRequest, AuthorizeRequest, etc.

If we compare an OMC to that of an HttpModule in the ASP.NET world, an OMC must be registered to the correct pre-defined pipeline event. For example, the HttpModule `MyModule` will get invoked when a request comes to the AuthenticateRequest stage in the pipeline:

```
public class MyModule : IHttpModule
{
    public void Dispose()
    {
        //clean-up code here.
    }
    public void Init(HttpApplication context)
    {
        // An example of how you can handle AuthenticateRequest events.
        context.AuthenticateRequest += ctx_AuthRequest;
    }
    void ctx_AuthRequest(object sender, EventArgs e)
    {
        // Handle event.
    }
}
```

In order for an OMC to participate in this same, event-based execution ordering, the Katana runtime code scans through the startup configuration and subscribes each of the middleware components to an integrated pipeline event. For example, the following OMC and registration code enables you to see the default event registration of middleware components. (For more detailed instructions on creating an OWIN startup class, see OWIN Startup Class Detection.)

1. Create an empty web application project and name it **owin2**.
2. From the Package Manager Console (PMC), run the following command:

   ```
   Install-Package Microsoft.Owin.Host.SystemWeb
   ```

3. Add an `OWIN Startup Class` and name it `Startup`. Replace the generated code with the following (the changes are highlighted):

```
using System;
using System.Threading.Tasks;
using Microsoft.Owin;
using Owin;
using System.Web;
using System.IO;
using Microsoft.Owin.Extensions;
[assembly: OwinStartup(typeof(owin2.Startup))]
namespace owin2
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            app.Use((context, next) =>
            {
                PrintCurrentIntegratedPipelineStage(context, "Middleware 1");
                return next.Invoke();
            });
            app.Use((context, next) =>
            {
                PrintCurrentIntegratedPipelineStage(context, "2nd MW");
                return next.Invoke();
            });
            app.Run(context =>
            {
                PrintCurrentIntegratedPipelineStage(context, "3rd MW");
                return context.Response.WriteAsync("Hello world");
            });
        }
        private void PrintCurrentIntegratedPipelineStage(IOwinContext context, string msg)
        {
            var currentIntegratedpipelineStage = HttpContext.Current.CurrentNotification;
            context.Get<TextWriter>("host.TraceOutput").WriteLine(
                "Current IIS event: " + currentIntegratedpipelineStage
                + " Msg: " + msg);
        }
    }
}
```

4. Hit F5 to run the app.

The Startup configuration sets up a pipeline with three middleware components, the first two displaying diagnostic information and the last one responding to events (and also displaying diagnostic information). The `PrintCurrentIntegratedPipelineStage` method displays the integrated pipeline event this middleware is invoked on and a message. The output windows displays the following:

```
Current IIS event: PreExecuteRequestHandler Msg: Middleware 1
Current IIS event: PreExecuteRequestHandler Msg: 2nd MW
Current IIS event: PreExecuteRequestHandler Msg: 3rd MW
```

The Katana runtime mapped each of the OWIN middleware components to PreExecuteRequestHandler by default, which corresponds to the IIS pipeline event PreRequestHandlerExecute.

Stage Markers

You can mark OMCs to execute at specific stages of the pipeline by using the `IAppBuilder UseStageMarker()` extension method. To run a set of middleware components during a particular stage, insert a stage marker right after the last component is the set during registration. There are rules on which stage of the pipeline you can execute middleware and the order components must run (The rules are explained later in the tutorial). Add the `UseStageMarker` method to the `Configuration` code as shown below:

```
public void Configuration(IAppBuilder app)
{
    app.Use((context, next) =>
    {
        PrintCurrentIntegratedPipelineStage(context, "Middleware 1");
        return next.Invoke();
    });
    app.Use((context, next) =>
    {
        PrintCurrentIntegratedPipelineStage(context, "2nd MW");
        return next.Invoke();
    });
    app.UseStageMarker(PipelineStage.Authenticate);
    app.Run(context =>
    {
        PrintCurrentIntegratedPipelineStage(context, "3rd MW");
        return context.Response.WriteAsync("Hello world");
    });
    app.UseStageMarker(PipelineStage.ResolveCache);
}
```

The `app.UseStageMarker(PipelineStage.Authenticate)` call configures all the previously registered middleware components (in this case, our two diagnostic components) to run on the authentication stage of the pipeline. The last middleware component (which displays diagnostics and responds to requests) will run on the `ResolveCache` stage (the ResolveRequestCache event).

Hit F5 to run the app.The output window shows the following:

```
Current IIS event: AuthenticateRequest Msg: Middleware 1
Current IIS event: AuthenticateRequest Msg: 2nd MW
Current IIS event: ResolveRequestCache Msg: 3rd MW
```

Stage Marker Rules

Owin middleware components (OMC) can be configured to run at the following OWIN pipeline stage events:

```
public enum PipelineStage
{
    Authenticate = 0,
    PostAuthenticate = 1,
    Authorize = 2,
    PostAuthorize = 3,
    ResolveCache = 4,
    PostResolveCache = 5,
    MapHandler = 6,
    PostMapHandler = 7,
    AcquireState = 8,
    PostAcquireState = 9,
    PreHandlerExecute = 10,
}
```

1. By default, OMCs run at the last event (`PreHandlerExecute`). That's why our first example code displayed "PreExecuteRequestHandler".
2. You can use the a `app.UseStageMarker` method to register a OMC to run earlier, at any stage of the OWIN pipeline listed in the `PipelineStage` enum.
3. The OWIN pipeline and the IIS pipeline is ordered, therefore calls to `app.UseStageMarker` must be in order. You cannot set the event handler to an event that precedes the last event registered with to

`app.UseStageMarker`. For example, *after* calling:

```
app.UseStageMarker(PipelineStage.Authorize);
```

calls to `app.UseStageMarker` passing `Authenticate` or `PostAuthenticate` will not be honored, and no exception will be thrown. OMCs run at the latest stage, which by default is `PreHandlerExecute`. The stage markers are used to make them to run earlier. If you specify stage markers out of order, we round to the earlier marker. In other words, adding a stage marker says "Run no later than stage X". OMC's run at the earliest stage marker added after them in the OWIN pipeline.

4. The earliest stage of calls to `app.UseStageMarker` wins. For example, if you switch the order of `app.UseStageMarker` calls from our previous example:

```
public void Configuration(IAppBuilder app)
{
    app.Use((context, next) =>
    {
        PrintCurrentIntegratedPipelineStage(context, "Middleware 1");
        return next.Invoke();
    });
    app.Use((context, next) =>
    {
        PrintCurrentIntegratedPipelineStage(context, "2nd MW");
        return next.Invoke();
    });
    app.UseStageMarker(PipelineStage.ResolveCache);
    app.Run(context =>
    {
        PrintCurrentIntegratedPipelineStage(context, "3rd MW");
        return context.Response.WriteAsync("Hello world");
    });
    app.UseStageMarker(PipelineStage.Authenticate);
}
```

The output window will display:

```
Current IIS event: AuthenticateRequest Msg: Middleware 1
Current IIS event: AuthenticateRequest Msg: 2nd MW
Current IIS event: AuthenticateRequest Msg: 3rd MW
```

The OMCs all run in the `AuthenticateRequest` stage, because the last OMC registered with the `Authenticate` event, and the `Authenticate` event precedes all other events.

Host OWIN in an Azure Worker Role

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This tutorial shows how to self-host OWIN in a Microsoft Azure worker role.

Open Web Interface for .NET (OWIN) defines an abstraction between .NET web servers and web applications. OWIN decouples the web application from the server, which makes OWIN ideal for self-hosting a web application in your own process, outside of IIS–for example, inside an Azure worker role.

In this tutorial, you'll learn how to self-host an OWIN applications inside a Microsoft Azure worker role. To learn more about worker roles, see Azure Execution Models.

Software versions used in the tutorial

- Visual Studio 2013
- Azure SDK for .NET 2.3
- Microsoft.Owin.Selfhost 2.1.0

Create a Microsoft Azure Project

Start Visual Studio with administrator privileges. Administrator privileges are needed to debug the application locally, using the Azure compute emulator.

On the **File** menu, click **New**, then click **Project**. From **Installed Templates**, under Visual C#, click **Cloud** and then click **Windows Azure Cloud Service**. Name the project "AzureApp" and click **OK**.

In the **New Windows Azure Cloud Service** dialog, double-click **Worker Role**. Leave the default name ("WorkerRole1"). This step adds a worker role to the solution. Click **OK**.

The Visual Studio solution that is created contains two projects:

- "AzureApp" defines the roles and configuration for the Azure application.
- "WorkerRole1" contains the code for the worker role.

In general, an Azure application can contain multiple roles, although this tutorial uses a single role.

Add the OWIN Self-Host Packages

From the **Tools** menu, click **NuGet Package Manager**, then click **Package Manager Console**.

In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.Owin.SelfHost
```

Add an HTTP Endpoint

In Solution Explorer, expand the AzureApp project. Expand the Roles node, right-click WorkerRole1, and select **Properties**.

Click **Endpoints**, and then click **Add Endpoint**.

In the **Protocol** dropdown list, select "http". In **Public Port** and **Private Port**, type 80. These port numbers can be different. The public port is what clients use when they send a request to the role.

Create the OWIN Startup Class

In Solution Explorer, right click the WorkerRole1 project and select **Add** / **Class** to add a new class. Name the class `Startup`.

Replace all of the boilerplate code with the following:

```
using Owin;

namespace WorkerRole1
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            app.UseWelcomePage("/");
        }
    }
}
```

The `UseWelcomePage` extension method adds a simple HTML page to your application, to verify the site is working.

Start the OWIN Host

Open the WorkerRole.cs file. This class defines the code that runs when the worker role is started and stopped.

Add the following using statement:

```
using Microsoft.Owin.Hosting;
```

Add an **IDisposable** member to the `WorkerRole` class:

```
public class WorkerRole : RoleEntryPoint
{
    private IDisposable _app = null;

    // ....
}
```

In the `OnStart` method, add the following code to start the host:

```
public override bool OnStart()
{
    ServicePointManager.DefaultConnectionLimit = 12;

    // New code:
    var endpoint = RoleEnvironment.CurrentRoleInstance.InstanceEndpoints["Endpoint1"];
    string baseUri = String.Format("{0}://{1}",
        endpoint.Protocol, endpoint.IPEndpoint);

    Trace.TraceInformation(String.Format("Starting OWIN at {0}", baseUri),
        "Information");

    _app = WebApp.Start<Startup>(new StartOptions(url: baseUri));
    return base.OnStart();
}
```

The **WebApp.Start** method starts the OWIN host. The name of the `Startup` class is a type parameter to the method. By convention, the host will call the `Configure` method of this class.

Override the `OnStop` to dispose of the *_app* instance:

```
public override void OnStop()
{
    if (_app != null)
    {
        _app.Dispose();
    }
    base.OnStop();
}
```

Here is the complete code for WorkerRole.cs:

```
using Microsoft.Owin.Hosting;
using Microsoft.WindowsAzure.ServiceRuntime;
using System;
using System.Diagnostics;
using System.Net;
using System.Threading;

namespace WorkerRole1
{
    public class WorkerRole : RoleEntryPoint
    {
        private IDisposable _app = null;

        public override void Run()
        {
            Trace.TraceInformation("WorkerRole entry point called", "Information");

            while (true)
            {
                Thread.Sleep(10000);
                Trace.TraceInformation("Working", "Information");
            }
        }

        public override bool OnStart()
        {
            ServicePointManager.DefaultConnectionLimit = 12;

            var endpoint = RoleEnvironment.CurrentRoleInstance.InstanceEndpoints["Endpoint1"];
            string baseUri = String.Format("{0}://{1}",
                endpoint.Protocol, endpoint.IPEndpoint);

            Trace.TraceInformation(String.Format("Starting OWIN at {0}", baseUri),
                "Information");

            _app = WebApp.Start<Startup>(new StartOptions(url: baseUri));
           return base.OnStart();
        }

        public override void OnStop()
        {
            if (_app != null)
            {
                _app.Dispose();
            }
            base.OnStop();
        }
    }
}
```

Build the solution, and press F5 to run the application locally in the Azure Compute Emulator. Depending on your firewall settings, you might need to allow the emulator through your firewall.

The compute emulator assigns a local IP address to the endpoint. You can find the IP address by viewing the Compute Emulator UI. Right-click the emulator icon in the task bar notification area, and select **Show Compute Emulator UI**.

Find the IP address under Service Deployments, deployment [id], Service Details. Open a web browser and navigate to http://*address*, where *address* is the IP address assigned by the compute emulator; for example, `http://127.0.0.1:80`. You should see the OWIN welcome page:

Deploy to Azure

For this step, you must have an Azure account. If you don't already have one, you can create a free trial account in just a couple of minutes. For details, see Microsoft Azure Free Trial.

In Solution Explorer, right-click the AzureApp project. Select **Publish**.

If you are not signed in to your Azure account, click **Sign In**.

After you are signed in, choose a subscription and click **Next**.

Enter a name for the cloud service and choose a region. Click **Create**.

Click **Publish**.

The Azure Activity Log window shows the progress of the deployment. When the app is deployed, browse to `http://appname.cloudapp.net/`, where *appname* is the name of your cloud service.

2/20/2020 • 15 minutes to read • Edit Online

On this page you will find whitepapers to help you install and configure ASP.NET, and to assist you to write secure, fast and flexible ASP.NET applications.

- ASP.NET 4
- ASP.NET Security Whitepapers
- Installation and Setup Whitepapers
- SQL Server Whitepapers
- General Whitepapers

ASP.NET 4

Information related to ASP.NET 4 and Visual Studio 2010.

ASP.NET MVC 4 Release Notes

This document describes new features and improvements introduced in the ASP.NET MVC 4 Developer Preview for Visual Studio 2010, as well as installation notes and known issues.

ASP.NET MVC 3 Release Notes

This document describes new features and improvements introduced in ASP.NET MVC 3, as well as installation notes and known issues.

ASP.NET 4 and Visual Studio 2010 Web Development Overview

Many exciting changes for ASP.NET are coming in the .NET Framework version 4. This document gives an overview of many of the new features that are included in the upcoming release.

ASP.NET 4 Beta 2 Breaking Changes

This document describes changes that have been made for the .NET Framework version 4 Beta 2 release (that is, the ASP.NET 4 Beta 2 release) that can potentially affect applications that were created using earlier releases, including the ASP.NET 4 Beta 1 release.

What's New in ASP.NET MVC 2

This document describes new features and improvements introduced in ASP.NET MVC 2.

Upgrading an ASP.NET MVC 1.0 Application to ASP.NET MVC 2

ASP.NET MVC 2 can be installed side by side with ASP.NET MVC 1.0 on the same server. This gives application developers flexibility in choosing when to upgrade an ASP.NET MVC 1.0 application to ASP.NET MVC 2. This document descibes both how to upgrade manually and with a wizard in Visual...

ASP.NET Security Whitepapers

Security is an important aspect of internet applications, and these whitepapers discuss how to design and implement secure ASP.NET applications.

Instrument ASP.NET 2.0 Applications for Security

This How To shows you how to use custom health monitoring events to instrument your ASP.NET application to

track security-related events and operations. ASP.NET version 2.0 provides health monitoring that includes instrumentation for many standard ...

Perform a Security Deployment Review for ASP.NET 2.0

This How To shows you how to perform a security deployment review for an ASP.NET 2.0 application to identify potential security vulnerabilities introduced by inappropriate configuration settings. The majority of the review process involves making...

Use ADAM for Roles in ASP.NET 2.0

This How To shows you how you can develop an ASP.NET Web site that uses Active Directory Application Mode (ADAM) to store ASP.NET roles. It shows you how to configure ADAM and the Authorization Manager (AzMan) policy store, how to create new roles and...

Use Authorization Manager (AzMan) with ASP.NET 2.0

This How To shows you how to use the Authorization Manager (AzMan) in conjunction with the ASP.NET role manager API to manage roles, check user role membership, and authorize roles to perform specific operations against an AzMan policy store. The How To...

Use Membership in ASP.NET 2.0

This How To shows how to use the membership feature in ASP.NET version 2.0 applications. It shows you how to use two different membership providers: the ActiveDirectoryMembershipProvider and the SqlMembershipProvider. The membership feature...

Use Role Manager in ASP.NET 2.0

This How To shows you how to use the ASP.NET 2.0 role manager. The role manager eases the task of managing roles and performing role-based authorization in your application. It shows how to configure the various role providers for use with your...

Use Windows Authentication in ASP.NET 2.0

This How To shows you how to configure and use Windows authentication in an ASP.NET Web application. Windows authentication is the preferred approach whenever users are a part of your Windows domain. This approach enables you to use an existing identity store...

Perform a Security Code Review for Managed Code (Baseline Activity)

This How To shows you how to perform security code reviews. This module presents the steps involved in the activity, and techniques for analyzing your results. Use this How To with "Security Question List: Managed Code (.NET Framework 2.0)" ...

Perform a Security Deployment Review for ASP.NET 2.0

This How To shows you how to perform a security deployment review for an ASP.NET 2.0 application to identify potential security vulnerabilities introduced by inappropriate configuration settings. The majority of the review process involves making...

Implement Kerberos Delegation for Windows 2000

Kerberos delegation allows you to flow an authenticated identity across multiple physical tiers of an application to support downstream authentication and authorization. This How To shows you the configuration steps required to make this work.

Use Impersonation and Delegation in ASP.NET 2.0

This How To shows you how and when you should use impersonation in ASP.NET 2.0 applications. By default, impersonation is turned off, and you can access resources by using the ASP.NET Web application's process identity.

However, you can use...

Create a Threat Model for a Web Application at Design Time

This How To describes an approach for creating a threat model for a Web application. The threat modeling activity helps you to model your security design so that you can expose potential security design flaws and vulnerabilities before you invest...

Forms Authentication

Protect Forms Authentication in ASP.NET 2.0

This How To shows you how to securely configure and use forms authentication with ASP.NET 2.0 applications. Key factors to consider include properly securing the authentication ticket and securing the user identity store and access to that store. ...

Use Forms Authentication with Active Directory in ASP.NET 2.0

This How To shows you how to use forms authentication with Microsoft® Active Directory® directory service by using the ActiveDirectoryMembershipProvider. The How To shows you how to configure the provider and create and authenticate users....

Use Forms Authentication with Active Directory in Multiple Domains in ASP.NET 2.0

This How To shows you how to use forms authentication with Microsoft® Active Directory® directory service by using the ActiveDirectoryMembershipProvider. The How To shows you how to configure the provider and create and authenticate users....

Use Forms Authentication with SQL Server in ASP.NET 2.0

This How To shows you how you can use forms authentication with the SQL Server membership provider. Forms authentication with SQL Server is most applicable in situations where users of your application are not part of your Windows domain, and as a result,...

Create GenericPrincipal Objects with Forms Authentication in ASP.NET 1.1

This How To shows you how to create and handle GenericPrincipal and FormsIdentity objects when using Forms authentication.

Use Forms Authentication with Active Directory in ASP.NET 1.1

This How To article shows you how to implement Forms authentication against an Active Directory credential store.

Use Forms Authentication with SQL Server in ASP.NET 1.1

This How To shows you how to implement Forms authentication against a SQL Server credential store. It also shows you how to store password digests in the database.

User Input Data Validation

Request Validation - Preventing Script Attacks

This paper describes the request validation feature of ASP.NET where, by default, the application is prevented from processing unencoded HTML content submitted to the server. This request validation feature can be disabled when the application has been...

Prevent Cross-Site Scripting in ASP.NET

This How To shows how you can help protect your ASP.NET applications from cross-site scripting attacks by using proper input validation techniques and by encoding the output. It also describes a number of other protection mechanisms that you can use in...

Protect From SQL Injection in ASP.NET

This How To shows a number of ways to help protect your ASP.NET application from SQL injection attacks. SQL injection can occur when an application uses input to construct dynamic SQL statements or when it uses stored procedures to connect to the...

Use Regular Expressions to Constrain Input in ASP.NET

This How To shows how you can use regular expressions within ASP.NET applications to constrain untrusted input. Regular expressions are a good way to validate text fields such as names, addresses, phone numbers, and other user information. You can use...

Code Access Security

Use Code Access Security in ASP.NET 2.0

This How To shows you how to select an appropriate trust level for your application, and where necessary, how to create a custom ASP.NET code access security policy file to define a custom trust level. You can use different code access security trust...

Create a Custom Encryption Permission

This How To describes how to create a custom code access security permission to control programmatic access to unmanaged encryption functionality that Win32® Data Protection API (DPAPI) provides. Use this custom permission with the managed DPAPI wrapper ...

Use Code Access Security Policy to Constrain an Assembly

An administrator can configure code access security policy to constrain the operations of .NET Framework code (assemblies). In this How To, you configure code access security policy to constrain the ability of an assembly to perform file I/O and restrict...

Communications Security

Set Up SSL on a Web Server

A Web server must be configured for SSL in order to support https connections from client applications. This How To shows you how to configure SSL on a Web Server.

Set Up Client Certificates

IIS supports client certificate authentication. This How To shows you how to configure a Web application to require client certificates. It also shows you how to install a certificate on a client computer and use it when calling the Web application.

Use IPSec for Filtering Ports and Authentication

Internet Protocol security (IPSec) is a protocol, not a service, that provides encryption, integrity, and authentication services for IP-based network traffic. Because IPSec provides server-to-server protection, you can use IPSec to counter internal threats...

Use IPSec to Provide Secure Communication Between Two Servers

IPSec is a technology provided by Windows 2000 that allows you to create encrypted channels between two servers. IPSec can be used to filter IP traffic and to authenticate servers. This How To shows you how to configure IPSec to provide a secure (encrypted) ...

Use SSL to Secure Communication with SQL Server

It is often vital for applications to be able to secure the data passed to and from a SQL Server database server. With SQL Server, you can use SSL to create an encrypted channel. This How To shows you how to install a certificate on the database server, ...

Call a Web Service Using Client Certificates from ASP.NET 1.1

This How To describes how you can pass a client certificate to a Web service for authentication from an ASP.NET Web application or from a Windows Forms application. You can install the client certificate in either the local machine store or the user store. If...

Call a Web Service Using SSL from ASP.NET 1.1

Secure Sockets Layer (SSL) encryption can be used to guarantee the integrity and confidentiality of the messages passed to and from a Web service. This How To shows you how to use SSL with Web services.

Cryptography

Create a DPAPI Library in .NET 1.1

This How To shows you how to create a managed class library that exposes DPAPI functionality to applications that want to encrypt data, for example, database connection strings and account credentials.

Create an Encryption Library in .NET 1.1

This How To shows you how to create a managed class library to provide encryption functionality for applications. It allows an application to choose the encryption algorithm. Supported algorithms include DES, Triple DES, RC2, and Rijndael.

Store an Encrypted Connection String in the Registry in ASP.NET 1.1

Applications may choose to store encrypted data such as connection strings and account credentials in the Windows registry. This How To shows you how to store and retrieve encrypted strings in the registry.

Use DPAPI (Machine Store) from ASP.NET 1.1

This How To shows you how to use DPAPI from an ASP.NET Web application or Web service to encrypt sensitive data.

Use DPAPI (User Store) from ASP.NET 1.1 with Enterprise Services

This How To shows you how to use DPAPI from an ASP.NET Web application or service to encrypt sensitive data. This How To uses DPAPI with the user store, which requires the use of an out of process Enterprise Services component.

Installation and Setup Whitepapers

These whitepapers provide step-by-step instructions for installing and configuring ASP.NET on your server.

Create a Service Account for an ASP.NET 2.0 Application

This How To shows you how to create and configure a custom least-privileged service account to run an ASP.NET Web application. By default, an ASP.NET application on Microsoft Windows Server 2003 and IIS 6.0 runs using the built-in Network Service ...

Improve Security When Hosting Multiple Applications in ASP.NET 2.0

This How To shows how you can isolate multiple applications from one another and from shared system resources in a Web hosting environment. The hosting environment might be a Web server provided by an Internet Service Provider (ISP) that hosts multiple ...

Use Medium Trust in ASP.NET 2.0

This How To shows you how to configure ASP.NET Web applications to run in medium trust. If you host multiple applications on the same server, you can use code access security and the medium trust level to provide application isolation. By setting ...

Use the Network Service Account to Access Resources in ASP.NET 2.0

This How To shows you how you can use the NT AUTHORITY\Network Service machine account to access local and network resources. By default on Windows Server 2003, ASP.NET applications run using this account's identity. It is a least privileged...

Use Protocol Transition and Constrained Delegation in ASP.NET 2.0

This How To shows you how to configure and use protocol transition and constrained delegation to allow your ASP.NET application to access network resources while impersonating the original caller. The Microsoft® Windows® 2000 operating system ...

ASP.NET Side-by-Side Execution of .NET Framework 1.0 and 1.1

This whitepaper describes how to install both .NET 1.0 and .NET 1.1 on your machine, allowing an ASP.NET Web application to run on either version of the framework.

ASP.NET Denied Access to IIS Directories

This whitepaper describes what you must do if a request to your ASP.NET application returns the error, "Denied Access to *DirectoryName* directory. Failed to start monitoring directory changes."

Running ASP.NET 1.1 with IIS 6.0

While Windows Server 2003 includes both IIS 6.0 and ASP.NET 1.1, these components are disabled by default. This whitepaper describes how to enable IIS 6.0 and ASP.NET 1.1, and recommends several configuration settings to get the optimal...

Fix for 'Server Application Unavailable' Error after Applying Security Update for IE

This paper describes the patch that fixes an issue with the MS03-32 Security Update for Internet Explorer that affects ASP.NET 1.0 applications running on Windows XP Professional.

Create a Custom Account To Run ASP.NET 1.1

ASP.NET Web applications usually run using the built-in ASPNET account. On occasion, you may want to use a custom account instead. This How To article shows you how to create a least privileged local account to run ASP.NET Web applications. ...

Configuration

Configure the Machine Key in ASP.NET 2.0

This How To explains the <machineKey> element in the Web.config file and shows how to configure the <machineKey> element to control tamper proofing and encryption of ViewState, forms authentication tickets, and role cookies. ViewState is signed...

Encrypt Configuration Sections in ASP.NET 2.0 Using DPAPI

This How To shows how to use the Windows Data Protection application programming interface (DPAPI) protected configuration provider and the Aspnet_regiis.exe tool to encrypt sections of your configuration files. You can use the Aspnet_regiis.exe tool to ...

Encrypt Configuration Sections in ASP.NET 2.0 Using RSA

This How To shows how to use the RSA Protected Configuration provider and the Aspnet_regiis.exe tool to encrypt sections of your configuration files. You can use Aspnet_regiis.exe tool to encrypt sensitive data, such as connection strings, held in the ...

Use Impersonation and Delegation in ASP.NET 2.0

This How To shows you how and when you should use impersonation in ASP.NET 2.0 applications. By default, impersonation is turned off, and you can access resources by using the ASP.NET Web application's process identity. However, you can use...

SQL Server Whitepapers

While ASP.NET works with a variety of databases, these whitepapers look specifically at connecting ASP.NET applications to SQL Server.

Connect to SQL Server Using SQL Authentication in ASP.NET 2.0

This How To shows you how to connect an ASP.NET application securely to Microsoft® SQL Server™ when database access authentication uses native SQL authentication. Windows authentication is the recommended way to connect to SQL Server because you...

Connect to SQL Server Using Windows Authentication in ASP.NET 2.0

This How To shows you how to connect to SQL Server 2000 using a Windows service account from an ASP.NET version 2.0 application. You should use Windows authentication instead of SQL authentication whenever possible because you avoid storing credentials in ...

Use SSL to Secure Communication with SQL Server 2000

It is often vital for applications to be able to secure the data passed to and from a SQL Server database server. With SQL Server, you can use SSL to create an encrypted channel. This How To shows you how to install a certificate on the database server,...

General Whitepapers

The following case study describes the process that was used to migrate Microsoft's .NET community websites from a traditional hosting environment to Microsoft Azure.

Migrating Microsoft's ASP.NET and IIS.NET Community Websites to Microsoft Azure

These whitepapers cover a variety of topics concerning ASP.NET.

Use Health Monitoring in ASP.NET 2.0

This How To shows you how to use health monitoring to instrument your application for a custom event. To create a custom health monitoring event, you create a class that derives from System.Web.Management.WebBaseEvent, configure the <healthMonitoring> ...

Implement Patch Management

This How To explains patch management, including how to keep single or multiple servers up to date. Additional software is not required, except for the tools available for download from Microsoft. Operations and security policy should adopt a patch management...

ASP.NET Server Controls for Silverlight in the Silverlight 3 SDK

The ASP.NET Server Controls for Silverlight ("ASP.NET Silverlight controls"), which are the ASP.NET MediaPlayer and Silverlight controls, have been removed from the Silverlight SDK for Silverlight version 3. This document provides guidance for developers who worked with these ASP.NET...

Building High Performance Web Applications

Learn how to use the new features in ASP.NET Ajax Library to build High Performance Web Applications

Work with SameSite cookies in ASP.NET

2/21/2020 • 12 minutes to read • Edit Online

By Rick Anderson

SameSite is an IETF draft standard designed to provide some protection against cross-site request forgery (CSRF) attacks. Originally drafted in 2016, the draft standard was updated in 2019. The updated standard is not backward compatible with the previous standard, with the following being the most noticeable differences:

- Cookies without SameSite header are treated as `SameSite=Lax` by default.
- `SameSite=None` must be used to allow cross-site cookie use.
- Cookies that assert `SameSite=None` must also be marked as `Secure`.
- Applications that use `<iframe>` may experience issues with `sameSite=Lax` or `sameSite=Strict` cookies because `<iframe>` is treated as cross-site scenarios.
- The value `SameSite=None` is not allowed by the 2016 standard and causes some implementations to treat such cookies as `SameSite=Strict`. See Supporting older browsers in this document.

The `SameSite=Lax` setting works for most application cookies. Some forms of authentication like OpenID Connect (OIDC) and WS-Federation default to POST based redirects. The POST based redirects trigger the SameSite browser protections, so SameSite is disabled for these components. Most OAuth logins are not affected due to differences in how the request flows.

Each ASP.NET component that emits cookies needs to decide if SameSite is appropriate.

See Known Issues for problems with applications after installing the 2019 .Net SameSite updates.

Using SameSite in ASP.NET 4.7.2 and 4.8

.Net 4.7.2 and 4.8 supports the 2019 draft standard for SameSite since the release of updates in December 2019. Developers are able to programmatically control the value of the SameSite header using the HttpCookie.SameSite property. Setting the `SameSite` property to `Strict`, `Lax`, or `None` results in those values being written on the network with the cookie. Setting it equal to `(SameSiteMode)(-1)` indicates that no SameSite header should be included on the network with the cookie. The HttpCookie.Secure Property, or 'requireSSL' in config files, can be used to mark the cookie as `Secure` or not.

New `HttpCookie` instances will default to `SameSite=(SameSiteMode)(-1)` and `Secure=false`. These defaults can be overridden in the `system.web/httpCookies` configuration section, where the string `"Unspecified"` is a friendly configuration-only syntax for `(SameSiteMode)(-1)`:

```
<configuration>
 <system.web>
  <httpCookies sameSite="[Strict|Lax|None|Unspecified]" requireSSL="[true|false]" />
 <system.web>
<configuration>
```

ASP.Net also issues four specific cookies of its own for these features: Anonymous Authentication, Forms Authentication, Session State, and Role Management. Instances of these cookies obtained in runtime can be manipulated using the `SameSite` and `Secure` properties just like any other HttpCookie instance. However, due to the patchwork emergence of the SameSite standard, configuration options for these four features cookies is inconsistent. The relevant configuration sections and attributes, with defaults, are shown below. If there is no `SameSite` or `Secure` related attribute for a feature, then the feature will fall back on the defaults configured in the

`system.web/httpCookies` section discussed above.

```
<configuration>
 <system.web>
  <anonymousIdentification cookieRequireSSL="false" /> <!-- No config attribute for SameSite -->
  <authentication>
   <forms cookieSameSite="Lax" requireSSL="false" />
  </authentication>
  <sessionState cookieSameSite="Lax" /> <!-- No config attribute for Secure -->
  <roleManager cookieRequireSSL="false" /> <!-- No config attribute for SameSite -->
 <system.web>
<configuration>
```

Note: 'Unspecified' is only available to `system.web/httpCookies@sameSite` at the moment. We hope to add similar syntax to the previously shown cookieSameSite attributes in future updates. Setting `(SameSiteMode)(-1)` in code still works on instances of these cookies.*

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

Retarget .NET apps

To target .NET 4.7.2 or later:

- Ensure *web.config* contains the following:

  ```
  <system.web>
    <compilation targetFramework="4.7.2"/>
    <httpRuntime targetFramework="4.7.2"/>
  </system.web>
  ```

- Verify the project file contains the correct TargetFrameworkVersion:

  ```
  <TargetFrameworkVersion>v4.7.2</TargetFrameworkVersion>
  ```

  The .NET Migration Guide has more details.

- Verify NuGet packages in the project are targeted at the correct framework version. You can verify the correct framework version by examining the *packages.config* file, for example:

  ```
  <?xml version="1.0" encoding="utf-8"?>
  <packages>
    <package id="Microsoft.AspNet.Mvc" version="5.2.7" targetFramework="net472" />
    <package id="Microsoft.ApplicationInsights" version="2.4.0" targetFramework="net451" />
  </packages>
  ```

  In the preceding *packages.config* file, the `Microsoft.ApplicationInsights` package:

  - Is targeted against .NET 4.5.1.
  - Should have its `targetFramework` attribute updated to `net472` if an updated package targeting your framework target exists.

.NET versions earlier than 4.7.2

Microsoft does not support .NET versions lower that 4.7.2 for writing the same-site cookie attribute. We have not found a reliable way to:

- Ensure the attribute is written correctly based on browser version.

- Intercept and adjust authentication and session cookies on older framework versions.

December patch behavior changes

The specific behavior change for .NET Framework is how the `SameSite` property interprets the `None` value:

- Before the patch a value of `None` meant:
  - Do not emit the attribute at all.
- After the patch:
  - A value of `None` it means "Emit the attribute with a value of `None`".
  - A `SameSite` value of `(SameSiteMode)(-1)` causes the attribute not to be emitted.

The default SameSite value for forms authentication and session state cookies was changed from `None` to `Lax`.

Summary of change impact on browsers

If you install the patch and issue a cookie with `SameSite.None`, one of two things will happen:

- Chrome v80 will treat this cookie according to the new implementation, and not enforce same site restrictions on the cookie.
- Any browser that has not been updated to support the new implementation will follow the old implementation. The old implementation says:
  - If you see a value you don't understand, ignore it and switch to strict same site restrictions.

So either the app breaks in Chrome, or you break in numerous other places.

History and changes

SameSite support was first implemented in .NET 4.7.2 using the 2016 draft standard.

The November 19, 2019 updates for Windows updated .NET 4.7.2+ from the 2016 standard to the 2019 standard. Additional updates are forthcoming for other versions of Windows. For more information, see KB articles that support SameSite in .NET Framework.

The 2019 draft of the SameSite specification:

- Is **not** backwards compatible with the 2016 draft. For more information, see Supporting older browsers in this document.
- Specifies cookies are treated as `SameSite=Lax` by default.
- Specifies cookies that explicitly assert `SameSite=None` in order to enable cross-site delivery should also be marked as `Secure`.
- Is supported by patches issued as described in the KB's listed above.
- Is scheduled to be enabled by Chrome by default in Feb 2020. Browsers started moving to this standard in 2019.

Known Issues

Because the 2016 and 2019 draft specifications are not compatible, the November 2019 .Net Framework update introduces some changes that may be breaking.

- Session State and Forms Authentication cookies are now written to the network as `Lax` instead of unspecified.
  - While most apps work with `SameSite=Lax` cookies, apps that POST across sites or applications that make use of `iframe` may find that their session state or forms authorization cookies aren't being used as expected. To remedy this, change the `cookieSameSite` value in the appropriate configuration section as discussed previously.
- HttpCookies that explicitly set `SameSite=None` in code or configuration now have that value written with the

cookie, whereas it was previously omitted. This may cause issues with older browsers that only support the 2016 draft standard.

- When targeting browsers supporting the 2019 draft standard with `SameSite=None` cookies, remember to also mark them `Secure` or they may not be recognized.
- To revert to the 2016 behavior of not writing `SameSite=None`, use the app setting `aspnet:SupressSameSiteNone=true`. Note that this will apply to all HttpCookies in the app.

Azure App Service—SameSite cookie handling

See Azure App Service—SameSite cookie handling and .NET Framework 4.7.2 patch for information about how Azure App Service is configuring SameSite behaviors in .Net 4.7.2 apps.

Supporting older browsers

The 2016 SameSite standard mandated that unknown values must be treated as `SameSite=Strict` values. Apps accessed from older browsers which support the 2016 SameSite standard may break when they get a SameSite property with a value of `None`. Web apps must implement browser detection if they intend to support older browsers. ASP.NET doesn't implement browser detection because User-Agents values are highly volatile and change frequently.

Microsoft's approach to fixing the problem is to help you implement browser detection components to strip the `sameSite=None` attribute from cookies if a browser is known to not support it. Google's advice was to issue double cookies, one with the new attribute, and one without the attribute at all. However we consider Google's advice limited. Some browsers, especially mobile browsers have very small limits on the number of cookies a site, or a domain name can send. Sending multiple cookies, especially large cookies like authentication cookies can reach the mobile browser limit very quickly, causing app failures that are hard to diagnose and fix. Furthermore as a framework there is a large ecosystem of third party code and components that may not be updated to use a double cookie approach.

The browser detection code used in the sample projects in is contained in two files

- C# SameSiteSupport.cs
- VB SameSiteSupport.vb

These detections are the most common browser agents we have seen that support the 2016 standard and for which the attribute needs to be completely removed. It isn't meant as a complete implementation:

- Your app may see browsers that our test sites do not.
- You should be prepared to add detections as necessary for your environment.

How you wire up the detection varies according the version of .NET and the web framework that you are using. The following code can be called at the HttpCookie call site:

```
private void CheckSameSite(HttpContext httpContext, HttpCookie cookie)
{
    if (cookie.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.UserAgent;
        if (BrowserDetection.DisallowsSameSiteNone(userAgent))
        {
            cookie.SameSite = (SameSiteMode)(-1);
        }
    }
}
```

See the following ASP.NET 4.7.2 SameSite cookie topics:

- C# MVC

- C# WebForms
- VB WebForms
- VB MVC

Ensuring your site redirects to HTTPS

For ASP.NET 4.x, WebForms and MVC, IIS's URL Rewrite feature can be used to redirect all requests to HTTPS. The following XML shows a sample rule:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <system.webServer>
    <rewrite>
      <rules>
        <rule name="Redirect to https" stopProcessing="true">
          <match url="(.*)"/>
          <conditions>
            <add input="{HTTPS}" pattern="Off"/>
            <add input="{REQUEST_METHOD}" pattern="^get$|^head$" />
          </conditions>
          <action type="Redirect" url="https://{HTTP_HOST}/{R:1}" redirectType="Permanent"/>
        </rule>
      </rules>
    </rewrite>
  </system.webServer>
</configuration>
```

In on-premises installations of IIS URL Rewrite is an optional feature that may need installing.

Test apps for SameSite problems

You must test your app with the browsers you support and go through your scenarios that involve cookies. Cookie scenarios typically involve

- Login forms
- External login mechanisms such as Facebook, Azure AD, OAuth and OIDC
- Pages that accept requests from other sites
- Pages in your app designed to be embedded in iframes

You should check that cookies are created, persisted and deleted correctly in your app.

Apps that interact with remote sites such as through third-party login need to:

- Test the interaction on multiple browsers.
- Apply the browser detection and mitigation discussed in this document.

Test web apps using a client version that can opt-in to the new SameSite behavior. Chrome, Firefox, and Chromium Edge all have new opt-in feature flags that can be used for testing. After your app applies the SameSite patches, test it with older client versions, especially Safari. For more information, see Supporting older browsers in this document.

Test with Chrome

Chrome 78+ gives misleading results because it has a temporary mitigation in place. The Chrome 78+ temporary mitigation allows cookies less than two minutes old. Chrome 76 or 77 with the appropriate test flags enabled provides more accurate results. To test the new SameSite behavior toggle `chrome://flags/#same-site-by-default-cookies` to **Enabled**. Older versions of Chrome (75 and below) are reported to fail with the new `None` setting. See Supporting older browsers in this document.

Google does not make older chrome versions available. Follow the instructions at Download Chromium to test

older versions of Chrome. Do **not** download Chrome from links provided by searching for older versions of chrome.

- Chromium 76 Win64
- Chromium 74 Win64
- If you're not using a 64bit version of Windows you can use the OmahaProxy viewer to look up which Chromium branch corresponds to Chrome 74 (v74.0.3729.108) using the instructions provided by Chromium.

Starting in Canary version `80.0.3975.0`, the Lax+POST temporary mitigation can be disabled for testing purposes using the new flag `--enable-features=SameSiteDefaultChecksMethodRigorously` to allow testing of sites and services in the eventual end state of the feature where the mitigation has been removed. For more information, see The Chromium Projects SameSite Updates

Test with Chrome 80+

Download a version of Chrome that supports their new attribute. At the time of writing, the current version is Chrome 80. Chrome 80 needs the flag `chrome://flags/#same-site-by-default-cookies` enabled to use the new behavior. You should also enable (`chrome://flags/#cookies-without-same-site-must-be-secure`) to test the upcoming behavior for cookies which have no sameSite attribute enabled. Chrome 80 is on target to make the switch to treat cookies without the attribute as `SameSite=Lax`, albeit with a timed grace period for certain requests. To disable the timed grace period Chrome 80 can be launched with the following command line argument:

```
--enable-features=SameSiteDefaultChecksMethodRigorously
```

Chrome 80 has warning messages in the browser console about missing sameSite attributes. Use F12 to open the browser console.

Test with Safari

Safari 12 strictly implemented the prior draft and fails when the new `None` value is in a cookie. `None` is avoided via the browser detection code Supporting older browsers in this document. Test Safari 12, Safari 13, and WebKit based OS style logins using MSAL, ADAL or whatever library you are using. The problem is dependent on the underlying OS version. OSX Mojave (10.14) and iOS 12 are known to have compatibility problems with the new SameSite behavior. Upgrading the OS to OSX Catalina (10.15) or iOS 13 fixes the problem. Safari does not currently have an opt-in flag for testing the new spec behavior.

Test with Firefox

Firefox support for the new standard can be tested on version 68+ by opting in on the `about:config` page with the feature flag `network.cookie.sameSite.laxByDefault`. There haven't been reports of compatibility issues with older versions of Firefox.

Test with Edge (Legacy) browser

Edge supports the old SameSite standard. Edge version 44+ doesn't have any known compatibility problems with the new standard.

Test with Edge (Chromium)

SameSite flags are set on the `edge://flags/#same-site-by-default-cookies` page. No compatibility issues were discovered with Edge Chromium.

Test with Electron

Versions of Electron include older versions of Chromium. For example, the version of Electron used by Teams is Chromium 66, which exhibits the older behavior. You must perform your own compatibility testing with the version of Electron your product uses. See Supporting older browsers.

Reverting SameSite patches

You can revert the updated sameSite behavior in .NET Framework apps to its previous behavior where the

sameSite attribute is not emitted for a value of `None`, and revert the authentication and session cookies to not emit the value. This should be viewed as an *extremely temporary fix*, as the Chrome changes will break any external POST requests or authentication for users using browsers which support the changes to the standard.

Reverting .NET 4.7.2 behavior

Update *web.config* to include the following configuration settings:

```
<configuration>
  <appSettings>
    <add key="aspnet:SuppressSameSiteNone" value="true" />
  </appSettings>

  <system.web>
    <authentication>
      <forms cookieSameSite="None" />
    </authentication>
    <sessionState cookieSameSite="None" />
  </system.web>
</configuration>
```

SameSite cookie sample for ASP.NET 4.7.2 C# MVC

2/20/2020 • 3 minutes to read • Edit Online

.NET Framework 4.7 has built-in support for the SameSite attribute, but it adheres to the original standard. The patched behavior changed the meaning of `SameSite.None` to emit the attribute with a value of `None`, rather than not emit the value at all. If you want to not emit the value you can set the `SameSite` property on a cookie to -1.

Writing the SameSite attribute

Following is an example of how to write a SameSite attribute on a cookie;

```
// Create the cookie
HttpCookie sameSiteCookie = new HttpCookie("SameSiteSample");

// Set a value for the cookieSite none.
// Note this will also require you to be running on HTTPS
sameSiteCookie.Value = "sample";

// Set the secure flag, which Chrome's changes will require for Same
sameSiteCookie.Secure = true;

// Set the cookie to HTTP only which is good practice unless you really do need
// to access it client side in scripts.
sameSiteCookie.HttpOnly = true;

// Add the SameSite attribute, this will emit the attribute with a value of none.
// To not emit the attribute at all set the SameSite property to -1.
sameSiteCookie.SameSite = SameSiteMode.None;

// Add the cookie to the response cookie collection
Response.Cookies.Add(sameSiteCookie);
```

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

The default sameSite attribute for session state is set in the 'cookieSameSite' parameter of the session settings in `web.config`

```
<system.web>
  <sessionState cookieSameSite="None">
  </sessionState>
</system.web>
```

MVC Authentication

OWIN MVC cookie based authentication uses a cookie manager to enable the changing of cookie attributes. The SameSiteCookieManager.cs is an implementation of such a class which you can copy into your own projects.

You must ensure your Microsoft.Owin components are all upgraded to version 4.1.0 or greater. Check your `packages.config` file to ensure all the version numbers match, for example.

```
<?xml version="1.0" encoding="utf-8"?>
<packages>
  <!-- other packages -->
  <package id="Microsoft.Owin.Host.SystemWeb" version="4.1.0" targetFramework="net472" />
  <package id="Microsoft.Owin.Security" version="4.1.0" targetFramework="net472" />
  <package id="Microsoft.Owin.Security.Cookies" version="4.1.0" targetFramework="net472" />
  <package id="Microsoft.Web.Infrastructure" version="1.0.0.0" targetFramework="net472" />
  <package id="Owin" version="1.0" targetFramework="net472" />
</packages>
```

The authentication components must then be configured to use the CookieManager in your startup class;

```
public void Configuration(IAppBuilder app)
{
    app.UseCookieAuthentication(new CookieAuthenticationOptions
    {
        CookieSameSite = SameSiteMode.None,
        CookieHttpOnly = true,
        CookieSecure = CookieSecureOption.Always,
        CookieManager = new SameSiteCookieManager(new SystemWebCookieManager())
    });
}
```

A cookie manager must be set on *each* component that supports it, this includes CookieAuthentication and OpenIdConnectAuthentication.

The SystemWebCookieManager is used to avoid known issues with response cookie integration.

Running the sample

If you run the sample project load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.

Name	Value	Domain	Path	Expires / Max-Age	Size	HttpOnly	Secure	SameSite
.ASPXAUTH	authentication	localhost	/	Session	23	✓	✓	None
sampleCookie	sample	localhost	/	Session	18	✓	✓	Lax

You can see from the image above that the cookie created by the sample when you click the "Create Cookies" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies you do not control

.NET 4.5.2 introduced a new event for intercepting the writing of headers, `Response.AddOnSendingHeaders`. This can be used to intercept cookies before they are returned to the client machine. In the sample we wire up the event to a static method which checks whether the browser supports the new sameSite changes, and if not, changes the cookies to not emit the attribute if the new `None` value has been set.

See global.asax for an example of hooking up the event and SameSiteCookieRewriter.cs for an example of handling the event and adjusting the cookie `sameSite` attribute which you can copy into your own code.

```
public static void FilterSameSiteNoneForIncompatibleUserAgents(object sender)
{
    HttpApplication application = sender as HttpApplication;
    if (application != null)
    {
        var userAgent = application.Context.Request.UserAgent;
        if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
        {
            HttpContext.Current.Response.AddOnSendingHeaders(context =>
            {
                var cookies = context.Response.Cookies;
                for (var i = 0; i < cookies.Count; i++)
                {
                    var cookie = cookies[i];
                    if (cookie.SameSite == SameSiteMode.None)
                    {
                        cookie.SameSite = (SameSiteMode)(-1); // Unspecified
                    }
                }
            });
        }
    }
}
```

You can change specific named cookie behavior in much the same way; the sample below adjust the default authentication cookie from `Lax` to `None` on browsers which support the `None` value, or removes the sameSite attribute on browsers which do not support `None`.

```
public static void AdjustSpecificCookieSettings()
{
    HttpContext.Current.Response.AddOnSendingHeaders(context =>
    {
        var cookies = context.Response.Cookies;
        for (var i = 0; i < cookies.Count; i++)
        {
            var cookie = cookies[i];
            // Forms auth: ".ASPXAUTH"
            // Session: "ASP.NET_SessionId"
            if (string.Equals(".ASPXAUTH", cookie.Name, StringComparison.Ordinal))
            {
                if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
                {
                    cookie.SameSite = -1;
                }
                else
                {
                    cookie.SameSite = SameSiteMode.None;
                }
                cookie.Secure = true;
            }
        }
    });
}
```

.NET SameSite Patches

SameSite cookie sample for ASP.NET 4.7.2 C# WebForms

2/20/2020 • 3 minutes to read • Edit Online

.NET Framework 4.7 has built-in support for the SameSite attribute, but it adheres to the original standard. The patched behavior changed the meaning of `SameSite.None` to emit the attribute with a value of `None`, rather than not emit the value at all. If you want to not emit the value you can set the `SameSite` property on a cookie to -1.

Writing the SameSite attribute

Following is an example of how to write a SameSite attribute on a cookie;

```
// Create the cookie
HttpCookie sameSiteCookie = new HttpCookie("SameSiteSample");

// Set a value for the cookie
sameSiteCookie.Value = "sample";

// Set the secure flag, which Chrome's changes will require for SameSite none.
// Note this will also require you to be running on HTTPS
sameSiteCookie.Secure = true;

// Set the cookie to HTTP only which is good practice unless you really do need
// to access it client side in scripts.
sameSiteCookie.HttpOnly = true;

// Add the SameSite attribute, this will emit the attribute with a value of none.
// To not emit the attribute at all set the SameSite property to -1.
sameSiteCookie.SameSite = SameSiteMode.None;

// Add the cookie to the response cookie collection
Response.Cookies.Add(sameSiteCookie);
```

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

The default sameSite attribute for a forms authentication cookie is set in the `cookieSameSite` parameter of the forms authentication settings in `web.config`

```
<system.web>
  <authentication mode="Forms">
    <forms name=".ASPXAUTH" loginUrl="~/" cookieSameSite="None" requireSSL="true">
    </forms>
  </authentication>
</system.web>
```

The default sameSite attribute for session state is also set in the 'cookieSameSite' parameter of the session settings in `web.config`

```
<system.web>
  <sessionState cookieSameSite="None">
  </sessionState>
</system.web>
```

The November 2019 update to .NET changed the default settings for Forms Authentication and Session to `lax` as is the most compatible setting, however if you embed pages into iframes you may need to revert this setting to None, and then add the interception code shown below to adjust the `none` behavior depending on browser capability.

Running the sample

If you run the sample project load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.

Name	Value	Domain	Path	Expires / Max-Age	Size	HttpOnly	Secure	SameSite
.ASPXAUTH	authentication	localhost	/	Session	23	✓	✓	None
sampleCookie	sample	localhost	/	Session	18	✓	✓	Lax

You can see from the image above that the cookie created by the sample when you click the "Create Cookies" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies you do not control

.NET 4.5.2 introduced a new event for intercepting the writing of headers, `Response.AddOnSendingHeaders`. This can be used to intercept cookies before they are returned to the client machine. In the sample we wire up the event to a static method which checks whether the browser supports the new sameSite changes, and if not, changes the cookies to not emit the attribute if the new `None` value has been set.

See global.asax for an example of hooking up the event and SameSiteCookieRewriter.cs for an example of handling the event and adjusting the cookie `sameSite` attribute.

```
public static void FilterSameSiteNoneForIncompatibleUserAgents(object sender)
{
    HttpApplication application = sender as HttpApplication;
    if (application != null)
    {
        var userAgent = application.Context.Request.UserAgent;
        if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
        {
            HttpContext.Current.Response.AddOnSendingHeaders(context =>
            {
                var cookies = context.Response.Cookies;
                for (var i = 0; i < cookies.Count; i++)
                {
                    var cookie = cookies[i];
                    if (cookie.SameSite == SameSiteMode.None)
                    {
                        cookie.SameSite = (SameSiteMode)(-1); // Unspecified
                    }
                }
            });
        }
    }
}
```

You can change specific named cookie behavior in much the same way; the sample below adjust the default authentication cookie from `Lax` to `None` on browsers which support the `None` value, or removes the sameSite attribute on browsers which do not support `None`.

```
public static void AdjustSpecificCookieSettings()
{
    HttpContext.Current.Response.AddOnSendingHeaders(context =>
    {
        var cookies = context.Response.Cookies;
        for (var i = 0; i < cookies.Count; i++)
        {
            var cookie = cookies[i];
            // Forms auth: ".ASPXAUTH"
            // Session: "ASP.NET_SessionId"
            if (string.Equals(".ASPXAUTH", cookie.Name, StringComparison.Ordinal))
            {
                if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
                {
                    cookie.SameSite = -1;
                }
                else
                {
                    cookie.SameSite = SameSiteMode.None;
                }
                cookie.Secure = true;
            }
        }
    });
}
```

.NET SameSite Patches

SameSite cookie sample for ASP.NET 4.7.2 VB WebForms

2/20/2020 • 3 minutes to read • Edit Online

.NET Framework 4.7 has built-in support for the SameSite attribute, but it adheres to the original standard. The patched behavior changed the meaning of `SameSite.None` to emit the attribute with a value of `None`, rather than not emit the value at all. If you want to not emit the value you can set the `SameSite` property on a cookie to -1.

Writing the SameSite attribute

Following is an example of how to write a SameSite attribute on a cookie;

```
' Create the cookie
Dim sameSiteCookie As New HttpCookie("sameSiteSample")

' Set a value for the cookie
sameSiteCookie.Value = "sample"

' Set the secure flag, which Chrome's changes will require for SameSite none.
' Note this will also require you to be running on HTTPS
sameSiteCookie.Secure = True

' Set the cookie to HTTP only which is good practice unless you really do need
' to access it client side in scripts.
sameSiteCookie.HttpOnly = True

' Expire the cookie in 1 minute
sameSiteCookie.Expires = Date.Now.AddMinutes(1)

' Add the SameSite attribute, this will emit the attribute with a value of none.
' To Not emit the attribute at all set the SameSite property to -1.
sameSiteCookie.SameSite = SameSiteMode.None

' Add the cookie to the response cookie collection
Response.Cookies.Add(sameSiteCookie)
```

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

The default sameSite attribute for a forms authentication cookie is set in the `cookieSameSite` parameter of the forms authentication settings in `web.config`

```
<system.web>
  <authentication mode="Forms">
    <forms name=".ASPXAUTH" loginUrl="~/" cookieSameSite="None" requireSSL="true">
    </forms>
  </authentication>
</system.web>
```

The default sameSite attribute for session state is also set in the 'cookieSameSite' parameter of the session settings in `web.config`

```
<system.web>
  <sessionState cookieSameSite="None">
  </sessionState>
</system.web>
```

The November 2019 update to .NET changed the default settings for Forms Authentication and Session to `lax` as is the most compatible setting, however if you embed pages into iframes you may need to revert this setting to None, and then add the interception code shown below to adjust the `none` behavior depending on browser capability.

Running the sample

If you run the sample project load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.

Name	Value	Domain	Path	Expires / Max-Age	Size	HttpOnly	Secure	SameSite
.ASPXAUTH	authentication	localhost	/	Session	23	✓	✓	None
sampleCookie	sample	localhost	/	Session	18	✓	✓	Lax

You can see from the image above that the cookie created by the sample when you click the "Create Cookies" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies you do not control

.NET 4.5.2 introduced a new event for intercepting the writing of headers, `Response.AddOnSendingHeaders`. This can be used to intercept cookies before they are returned to the client machine. In the sample we wire up the event to a static method which checks whether the browser supports the new sameSite changes, and if not, changes the cookies to not emit the attribute if the new `None` value has been set.

See global.asax for an example of hooking up the event and SameSiteCookieRewriter.cs for an example of handling the event and adjusting the cookie `sameSite` attribute.

```
Sub FilterSameSiteNoneForIncompatibleUserAgents(ByVal sender As Object)
    Dim application As HttpApplication = TryCast(sender, HttpApplication)

    If application IsNot Nothing Then
        Dim userAgent = application.Context.Request.UserAgent

        If SameSite.DisallowsSameSiteNone(userAgent) Then
            application.Response.AddOnSendingHeaders(
                Function(context)
                    Dim cookies = context.Response.Cookies

                    For i = 0 To cookies.Count - 1
                        Dim cookie = cookies(i)

                        If cookie.SameSite = SameSiteMode.None Then
                            cookie.SameSite = CType((-1), SameSiteMode)
                        End If
                    Next
                End Function)
        End If
    End If
End Sub
```

You can change specific named cookie behavior in much the same way; the sample below adjust the default authentication cookie from `Lax` to `None` on browsers which support the `None` value, or removes the sameSite attribute on browsers which do not support `None`.

```
Public Shared Sub AdjustSpecificCookieSettings()
    HttpContext.Current.Response.AddOnSendingHeaders(Function(context)
            Dim cookies = context.Response.Cookies

            For i = 0 To cookies.Count - 1
            Dim cookie = cookies(i)

            If String.Equals(".ASPXAUTH", cookie.Name, StringComparison.Ordinal) Then

                If SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent) Then
                    cookie.SameSite = -1
                Else
                    cookie.SameSite = SameSiteMode.None
                End If

                cookie.Secure = True
            End If
            Next
        End Function)
End Sub
```

.NET SameSite Patches

SameSite cookie sample for ASP.NET 4.7.2 VB MVC

2/20/2020 • 3 minutes to read • Edit Online

.NET Framework 4.7 has built-in support for the SameSite attribute, but it adheres to the original standard. The patched behavior changed the meaning of `SameSite.None` to emit the attribute with a value of `None`, rather than not emit the value at all. If you want to not emit the value you can set the `SameSite` property on a cookie to -1.

Writing the SameSite attribute

Following is an example of how to write a SameSite attribute on a cookie;

```
' Create the cookie
Dim sameSiteCookie As New HttpCookie("sameSiteSample")

' Set a value for the cookie
sameSiteCookie.Value = "sample"

' Set the secure flag, which Chrome's changes will require for SameSite none.
' Note this will also require you to be running on HTTPS
sameSiteCookie.Secure = True

' Set the cookie to HTTP only which is good practice unless you really do need
' to access it client side in scripts.
sameSiteCookie.HttpOnly = True

' Expire the cookie in 1 minute
sameSiteCookie.Expires = Date.Now.AddMinutes(1)

' Add the SameSite attribute, this will emit the attribute with a value of none.
' To Not emit the attribute at all set the SameSite property to -1.
sameSiteCookie.SameSite = SameSiteMode.None

' Add the cookie to the response cookie collection
Response.Cookies.Add(sameSiteCookie)
```

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

The default sameSite attribute for session state is set in the 'cookieSameSite' parameter of the session settings in `web.config`

```
<system.web>
  <sessionState cookieSameSite="None">
  </sessionState>
</system.web>
```

MVC Authentication

OWIN MVC cookie based authentication uses a cookie manager to enable the changing of cookie attributes. The SameSiteCookieManager.vb is an implementation of such a class which you can copy into your own projects.

You must ensure your Microsoft.Owin components are all upgraded to version 4.1.0 or greater. Check your `packages.config` file to ensure all the version numbers match, for example.

```
<?xml version="1.0" encoding="utf-8"?>
<packages>
  <!-- other packages -->
  <package id="Microsoft.Owin.Host.SystemWeb" version="4.1.0" targetFramework="net472" />
  <package id="Microsoft.Owin.Security" version="4.1.0" targetFramework="net472" />
  <package id="Microsoft.Owin.Security.Cookies" version="4.1.0" targetFramework="net472" />
  <package id="Microsoft.Web.Infrastructure" version="1.0.0.0" targetFramework="net472" />
  <package id="Owin" version="1.0" targetFramework="net472" />
</packages>
```

The authentication components must be configured to use the CookieManager in your startup class;

```
Public Sub Configuration(app As IAppBuilder)
    app.UseCookieAuthentication(New CookieAuthenticationOptions() With {
        .CookieSameSite = SameSiteMode.None,
        .CookieHttpOnly = True,
        .CookieSecure = CookieSecureOption.Always,
        .CookieManager = New SameSiteCookieManager(New SystemWebCookieManager())
    })
End Sub
```

A cookie manager must be set on *each* component that supports it, this includes CookieAuthentication and OpenIdConnectAuthentication.

The SystemWebCookieManager is used to avoid known issues with response cookie integration.

Running the sample

If you run the sample project please load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.

Name	Value	Domain	Path	Expires / Max-Age	Size	HttpOnly	Secure	SameSite
.ASPXAUTH	authentication	localhost	/	Session	23	✓	✓	None
sampleCookie	sample	localhost	/	Session	18	✓	✓	Lax

You can see from the image above that the cookie created by the sample when you click the "Create SameSite Cookie" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies you do not control

.NET 4.5.2 introduced a new event for intercepting the writing of headers, `Response.AddOnSendingHeaders`. This can be used to intercept cookies before they are returned to the client machine. In the sample we wire up the event to a static method which checks whether the browser supports the new sameSite changes, and if not, changes the cookies to not emit the attribute if the new `None` value has been set.

See global.asax for an example of hooking up the event and SameSiteCookieRewriter.vb for an example of handling the event and adjusting the cookie `sameSite` attribute which you can copy into your own code.

```
Sub FilterSameSiteNoneForIncompatibleUserAgents(ByVal sender As Object)
    Dim application As HttpApplication = TryCast(sender, HttpApplication)

    If application IsNot Nothing Then
        Dim userAgent = application.Context.Request.UserAgent

        If SameSite.DisallowsSameSiteNone(userAgent) Then
            application.Response.AddOnSendingHeaders(
                Function(context)
                    Dim cookies = context.Response.Cookies

                    For i = 0 To cookies.Count - 1
                        Dim cookie = cookies(i)

                        If cookie.SameSite = SameSiteMode.None Then
                            cookie.SameSite = CType((-1), SameSiteMode)
                        End If
                    Next
                End Function)
        End If
    End If
End Sub
```

You can change specific named cookie behavior in much the same way; the sample below adjust the default authentication cookie from `Lax` to `None` on browsers which support the `None` value, or removes the sameSite attribute on browsers which do not support `None`.

```
Public Shared Sub AdjustSpecificCookieSettings()
    HttpContext.Current.Response.AddOnSendingHeaders(Function(context)
            Dim cookies = context.Response.Cookies

            For i = 0 To cookies.Count - 1
            Dim cookie = cookies(i)

            If String.Equals(".ASPXAUTH", cookie.Name, StringComparison.Ordinal) Then

                If SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent) Then
                    cookie.SameSite = -1
                Else
                    cookie.SameSite = SameSiteMode.None
                End If

                cookie.Secure = True
            End If
            Next
        End Function)
End Sub
```

Contents

Core Services

Web.config File Refactoring
Extensible Output Caching
Auto-Start Web Applications
Permanently Redirecting a Page
Shrinking Session State
Expanding the Range of Allowable URLs
Extensible Request Validation
Object Caching and Object Caching Extensibility
Extensible HTML, URL, and HTTP Header Encoding
Performance Monitoring for Individual Applications in a Single Worker Process
Multi-Targeting

Ajax

jQuery Included with Web Forms and MVC
Content Delivery Network Support
ScriptManager Explicit Scripts

Web Forms

Setting Meta Tags with the Page.MetaKeywords and Page.MetaDescription Properties
Enabling View State for Individual Controls
Changes to Browser Capabilities
Routing in ASP.NET 4
Setting Client IDs
Persisting Row Selection in Data Controls
ASP.NET Chart Control
Filtering Data with the QueryExtender Control
Html Encoded Code Expressions
Project Template Changes
CSS Improvements
Hiding div Elements Around Hidden Fields
Rendering an Outer Table for Templated Controls
ListView Control Enhancements
CheckBoxList and RadioButtonList Control Enhancements
Menu Control Improvements
Wizard and CreateUserWizard Controls 56

ASP.NET MVC

Areas Support
Data-Annotation Attribute Validation Support
Templated Helpers

Dynamic Data
Enabling Dynamic Data for Existing Projects
Declarative DynamicDataManager Control Syntax
Entity Templates
New Field Templates for URLs and E-mail Addresses
Creating Links with the DynamicHyperLink Control
Support for Inheritance in the Data Model
Support for Many-to-Many Relationships (Entity Framework Only)
New Attributes to Control Display and Support Enumerations
Enhanced Support for Filters

Visual Studio 2010 Web Development Improvements
Improved CSS Compatibility
HTML and JavaScript Snippets
JavaScript IntelliSense Enhancements

Web Application Deployment with Visual Studio 2010
Web Packaging
Web.config Transformation
Database Deployment
One-Click Publish for Web Applications
Resources

Disclaimer

Core Services

ASP.NET 4 introduces a number of features that improve core ASP.NET services such as output caching and session-state storage.

Web.config File Refactoring

The `Web.config` file that contains the configuration for a Web application has grown considerably over the past few releases of the .NET Framework as new features have been added, such as Ajax, routing, and integration with IIS 7. This has made it harder to configure or start new Web applications without a tool like Visual Studio. In .the NET Framework 4, the major configuration elements have been moved to the `machine.config` file, and applications now inherit these settings. This allows the `Web.config` file in ASP.NET 4 applications either to be empty or to contain just the following lines, which specify for Visual Studio what version of the framework the application is targeting:

```
<?xml version="1.0"?>
  <configuration>
   <system.web>
    <compilation targetFramework="4.0" />
   </system.web>
  </configuration>
```

Extensible Output Caching

Since the time that ASP.NET 1.0 was released, output caching has enabled developers to store the generated output of pages, controls, and HTTP responses in memory. On subsequent Web requests, ASP.NET can serve content more quickly by retrieving the generated output from memory instead of regenerating the output from scratch. However, this approach has a limitation — generated content always has to be stored in memory, and on servers

that are experiencing heavy traffic, the memory consumed by output caching can compete with memory demands from other portions of a Web application.

ASP.NET 4 adds an extensibility point to output caching that enables you to configure one or more custom output-cache providers. Output-cache providers can use any storage mechanism to persist HTML content. This makes it possible to create custom output-cache providers for diverse persistence mechanisms, which can include local or remote disks, cloud storage, and distributed cache engines.

You create a custom output-cache provider as a class that derives from the new *System.Web.Caching.OutputCacheProvider* type. You can then configure the provider in the `Web.config` file by using the new *providers* subsection of the *outputCache* element, as shown in the following example:

```
<caching>
  <outputCache defaultProvider="AspNetInternalProvider">
    <providers>
      <add name="DiskCache"
          type="Test.OutputCacheEx.DiskOutputCacheProvider, DiskCacheProvider"/>
    </providers>
  </outputCache>

</caching>
```

By default in ASP.NET 4, all HTTP responses, rendered pages, and controls use the in-memory output cache, as shown in the previous example, where the *defaultProvider* attribute is set to AspNetInternalProvider. You can change the default output-cache provider used for a Web application by specifying a different provider name for *defaultProvider*.

In addition, you can select different output-cache providers per control and per request. The easiest way to choose a different output-cache provider for different Web user controls is to do so declaratively by using the new *providerName* attribute in a control directive, as shown in the following example:

```
<%@ OutputCache Duration="60" VaryByParam="None" providerName="DiskCache" %>
```

Specifying a different output cache provider for an HTTP request requires a little more work. Instead of declaratively specifying the provider, you override the new *GetOuputCacheProviderName* method in the `Global.asax` file to programmatically specify which provider to use for a specific request. The following example shows how to do this.

```
public override string GetOutputCacheProviderName(HttpContext context)
{
    if (context.Request.Path.EndsWith("Advanced.aspx"))
       return "DiskCache";
    else
        return base.GetOutputCacheProviderName(context);
}
```

With the addition of output-cache provider extensibility to ASP.NET 4, you can now pursue more aggressive and more intelligent output-caching strategies for your Web sites. For example, it is now possible to cache the "Top 10" pages of a site in memory, while caching pages that get lower traffic on disk. Alternatively, you can cache every vary-by combination for a rendered page, but use a distributed cache so that the memory consumption is offloaded from front-end Web servers.

Auto-Start Web Applications

Some Web applications need to load large amounts of data or perform expensive initialization processing before serving the first request. In earlier versions of ASP.NET, for these situations you had to devise custom approaches to "wake up" an ASP.NET application and then run initialization code during the *Application_Load* method in the

`Global.asax` file.

A new scalability feature named *auto-start* that directly addresses this scenario is available when ASP.NET 4 runs on IIS 7.5 on Windows Server 2008 R2. The auto-start feature provides a controlled approach for starting up an application pool, initializing an ASP.NET application, and then accepting HTTP requests.

> **NOTE**
>
> IIS Application Warm-Up Module for IIS 7.5
>
> The IIS team has released the first beta test version of the Application Warm-Up Module for IIS 7.5. This makes warming up your applications even easier than previously described. Instead of writing custom code, you specify the URLs of resources to execute before the Web application accepts requests from the network. This warm-up occurs during startup of the IIS service (if you configured the IIS application pool as *AlwaysRunning*) and when an IIS worker process recycles. During recycle, the old IIS worker process continues to execute requests until the newly spawned worker process is fully warmed up, so that applications experience no interruptions or other issues due to unprimed caches. Note that this module works with any version of ASP.NET, starting with version 2.0.
>
> For more information, see Application Warm-Up on the IIS.net Web site. For a walkthrough that illustrates how to use the warm-up feature, see Getting Started with the IIS 7.5 Application Warm-Up Module on the IIS.net Web site.

To use the auto-start feature, an IIS administrator sets an application pool in IIS 7.5 to be automatically started by using the following configuration in the `applicationHost.config` file:

```
<applicationpools>
  <add name="MyApplicationPool" startMode="AlwaysRunning" />
</applicationpools>
```

Because a single application pool can contain multiple applications, you specify individual applications to be automatically started by using the following configuration in the `applicationHost.config` file:

```
<sites>
  <site name="MySite" id="1">
    <application path="/"
      serviceAutoStartEnabled="true"
      serviceAutoStartProvider="PrewarmMyCache" >
      <!-- Additional content -->
    </application>
  </site>

</sites>

<!-- Additional content -->

<serviceautostartproviders>
  <add name="PrewarmMyCache"
    type="MyNamespace.CustomInitialization, MyLibrary" />
</serviceautostartproviders>
```

When an IIS 7.5 server is cold-started or when an individual application pool is recycled, IIS 7.5 uses the information in the `applicationHost.config` file to determine which Web applications need to be automatically started. For each application that is marked for auto-start, IIS7.5 sends a request to ASP.NET 4 to start the application in a state during which the application temporarily does not accept HTTP requests. When it is in this state, ASP.NET instantiates the type defined by the *serviceAutoStartProvider* attribute (as shown in the previous example) and calls into its public entry point.

You create a managed auto-start type with the necessary entry point by implementing the *IProcessHostPreloadClient* interface, as shown in the following example:

```
public class CustomInitialization : System.Web.Hosting.IProcessHostPreloadClient
{
    public void Preload(string[] parameters)
    {
        // Perform initialization.
    }
}
```

After your initialization code runs in the *Preload* method and the method returns, the ASP.NET application is ready to process requests.

With the addition of auto-start to IIS .5 and ASP.NET 4, you now have a well-defined approach for performing expensive application initialization prior to processing the first HTTP request. For example, you can use the new auto-start feature to initialize an application and then signal a load-balancer that the application was initialized and ready to accept HTTP traffic.

Permanently Redirecting a Page

It is common practice in Web applications to move pages and other content around over time, which can lead to an accumulation of stale links in search engines. In ASP.NET, developers have traditionally handled requests to old URLs by using by using the *Response.Redirect* method to forward a request to the new URL. However, the *Redirect* method issues an HTTP 302 Found (temporary redirect) response, which results in an extra HTTP round trip when users attempt to access the old URLs.

ASP.NET 4 adds a new *RedirectPermanent* helper method that makes it easy to issue HTTP 301 Moved Permanently responses, as in the following example:

```
RedirectPermanent("/newpath/foroldcontent.aspx");
```

Search engines and other user agents that recognize permanent redirects will store the new URL that is associated with the content, which eliminates the unnecessary round trip made by the browser for temporary redirects.

Shrinking Session State

ASP.NET provides two default options for storing session state across a Web farm: a session-state provider that invokes an out-of-process session-state server, and a session-state provider that stores data in a Microsoft SQL Server database. Because both options involve storing state information outside a Web application's worker process, session state has to be serialized before it is sent to remote storage. Depending on how much information a developer saves in session state, the size of the serialized data can grow quite large.

ASP.NET 4 introduces a new compression option for both kinds of out-of-process session-state providers. When the *compressionEnabled* configuration option shown in the following example is set to *true*, ASP.NET will compress (and decompress) serialized session state by using the .NET Framework *System.IO.Compression.GZipStream* class.

```
<sessionState
  mode="SqlServer"
  sqlConnectionString="data source=dbserver;Initial Catalog=aspnetstate"
  allowCustomSqlDatabase="true"
  compressionEnabled="true"
/>
```

With the simple addition of the new attribute to the `Web.config` file, applications with spare CPU cycles on Web servers can realize substantial reductions in the size of serialized session-state data.

Expanding the Range of Allowable URLs

ASP.NET 4 introduces new options for expanding the size of application URLs. Previous versions of ASP.NET constrained URL path lengths to 260 characters, based on the NTFS file-path limit. In ASP.NET 4, you have the

option to increase (or decrease) this limit as appropriate for your applications, using two new *httpRuntime* configuration attributes. The following example shows these new attributes.

```
<httpRuntime maxUrlLength="260" maxQueryStringLength="2048" />
```

To allow longer or shorter paths (the portion of the URL that does not include protocol, server name, and query string), modify the *maxUrlLength* attribute. To allow longer or shorter query strings, modify the value of the *maxQueryStringLength* attribute.

ASP.NET 4 also enables you to configure the characters that are used by the URL character check. When ASP.NET finds an invalid character in the path portion of a URL, it rejects the request and issues an HTTP 400 error. In previous versions of ASP.NET, the URL character checks were limited to a fixed set of characters. In ASP.NET 4, you can customize the set of valid characters using the new *requestPathInvalidCharacters* attribute of the *httpRuntime* configuration element, as shown in the following example:

```
<httpRuntime requestPathInvalidCharacters="&lt;,&gt;,*,%,&amp;,:,\,?"  />
```

By default, the *requestPathInvalidCharacters* attribute defines eight characters as invalid. (In the string that is assigned to *requestPathInvalidCharacters* by default, the less than (<), greater than (>), and ampersand (&) characters are encoded, because the `Web.config` file is an XML file.) You can customize the set of invalid characters as needed.

> **NOTE**
>
> Note ASP.NET 4 always rejects URL paths that contain characters in the ASCII range of 0x00 to 0x1F, because those are invalid URL characters as defined in RFC 2396 of the IETF (http://www.ietf.org/rfc/rfc2396.txt). On versions of Windows Server that run IIS 6 or higher, the http.sys protocol device driver automatically rejects URLs with these characters.

Extensible Request Validation

ASP.NET request validation searches incoming HTTP request data for strings that are commonly used in cross-site scripting (XSS) attacks. If potential XSS strings are found, request validation flags the suspect string and returns an error. The built-in request validation returns an error only when it finds the most common strings used in XSS attacks. Previous attempts to make the XSS validation more aggressive resulted in too many false positives. However, customers might want request validation that is more aggressive, or conversely might want to intentionally relax XSS checks for specific pages or for specific types of requests.

In ASP.NET 4, the request validation feature has been made extensible so that you can use custom request-validation logic. To extend request validation, you create a class that derives from the new *System.Web.Util.RequestValidator* type, and you configure the application (in the *httpRuntime* section of the `Web.config` file) to use the custom type. The following example shows how to configure a custom request-validation class:

```
<httpRuntime requestValidationType="Samples.MyValidator, Samples" />
```

The new *requestValidationType* attribute requires a standard .NET Framework type identifier string that specifies the class that provides custom request validation. For each request, ASP.NET invokes the custom type to process each piece of incoming HTTP request data. The incoming URL, all the HTTP headers (both cookies and custom headers), and the entity body are all available for inspection by a custom request validation class like that shown in the following example:

```
public class CustomRequestValidation : RequestValidator
{
    protected override bool IsValidRequestString(
      HttpContext context, string value,
      RequestValidationSource requestValidationSource,
      string collectionKey,
      out int validationFailureIndex)
    {...}
 }
```

For cases where you do not want to inspect a piece of incoming HTTP data, the request-validation class can fall back to let the ASP.NET default request validation run by simply calling *base.IsValidRequestString*.

Object Caching and Object Caching Extensibility

Since its first release, ASP.NET has included a powerful in-memory object cache (*System.Web.Caching.Cache*). The cache implementation has been so popular that it has been used in non-Web applications. However, it is awkward for a Windows Forms or WPF application to include a reference to `System.Web.dll` just to be able to use the ASP.NET object cache.

To make caching available for all applications, the .NET Framework 4 introduces a new assembly, a new namespace, some base types, and a concrete caching implementation. The new `System.Runtime.Caching.dll` assembly contains a new caching API in the *System.Runtime.Caching* namespace. The namespace contains two core sets of classes:

- Abstract types that provide the foundation for building any type of custom cache implementation.
- A concrete in-memory object cache implementation (the *System.Runtime.Caching.MemoryCache* class).

The new *MemoryCache* class is modeled closely on the ASP.NET cache, and it shares much of the internal cache engine logic with ASP.NET. Although the public caching APIs in *System.Runtime.Caching* have been updated to support development of custom caches, if you have used the ASP.NET *Cache* object, you will find familiar concepts in the new APIs.

An in-depth discussion of the new *MemoryCache* class and supporting base APIs would require an entire document. However, the following example gives you an idea of how the new cache API works. The example was written for a Windows Forms application, without any dependency on `System.Web.dll`.

```
private void btnGet_Click(object sender, EventArgs e)
{
    //Obtain a reference to the default MemoryCache instance.
    //Note that you can create multiple MemoryCache(s) inside
    //of a single application.
    ObjectCache cache = MemoryCache.Default;

    //In this example the cache is storing the contents of a file string
    fileContents = cache["filecontents"] as string;

    //If the file contents are not currently in the cache, then
    //the contents are read from disk and placed in the cache.
    if (fileContents == null)
    {
        //A CacheItemPolicy object holds all the pieces of cache
        //dependency and cache expiration metadata related to a single
        //cache entry.
        CacheItemPolicy policy = new CacheItemPolicy();

        //Build up the information necessary to create a file dependency.
        //In this case we just need the file path of the file on disk.
        List filePaths = new List();
        filePaths.Add("c:\\data.txt");

        //In the new cache API, dependencies are called "change monitors".
        //For this example we want the cache entry to be automatically expired
        //if the contents on disk change. A HostFileChangeMonitor provides
        //this functionality.
        policy.ChangeMonitors.Add(new HostFileChangeMonitor(filePaths));

        //Fetch the file's contents
        fileContents = File.ReadAllText("c:\\data.txt");

        //And then store the file's contents in the cache
        cache.Set("filecontents", fileContents, policy);

    }
    MessageBox.Show(fileContents);
}
```

Extensible HTML, URL, and HTTP Header Encoding

In ASP.NET 4, you can create custom encoding routines for the following common text-encoding tasks:

- HTML encoding.
- URL encoding.
- HTML attribute encoding.
- Encoding outbound HTTP headers.

You can create a custom encoder by deriving from the new *System.Web.Util.HttpEncoder* type and then configuring ASP.NET to use the custom type in the *httpRuntime* section of the `Web.config` file, as shown in the following example:

```
<httpRuntime encoderType="Samples.MyCustomEncoder, Samples" />
```

After a custom encoder has been configured, ASP.NET automatically calls the custom encoding implementation whenever public encoding methods of the *System.Web.HttpUtility* or *System.Web.HttpServerUtility* classes are called. This lets one part of a Web development team create a custom encoder that implements aggressive character encoding, while the rest of the Web development team continues to use the public ASP.NET encoding APIs. By centrally configuring a custom encoder in the *httpRuntime* element, you are guaranteed that all text-encoding calls from the public ASP.NET encoding APIs are routed through the custom encoder.

Performance Monitoring for Individual Applications in a Single Worker Process

In order to increase the number of Web sites that can be hosted on a single server, many hosters run multiple ASP.NET applications in a single worker process. However, if multiple applications use a single shared worker process, it is difficult for server administrators to identify an individual application that is experiencing problems.

ASP.NET 4 leverages new resource-monitoring functionality introduced by the CLR. To enable this functionality, you can add the following XML configuration snippet to the `aspnet.config` configuration file.

```
<?xml version="1.0" encoding="UTF-8" ?>
<configuration>
  <runtime>
    <appDomainResourceMonitoring enabled="true"/>
  </runtime>

</configuration>
```

> **NOTE**
>
> Note The `aspnet.config` file is in the directory where the .NET Framework is installed. It is not the `Web.config` file.

When the *appDomainResourceMonitoring* feature has been enabled, two new performance counters are available in the "ASP.NET Applications" performance category: *% Managed Processor Time* and *Managed Memory Used*. Both of these performance counters use the new CLR application-domain resource management feature to track estimated CPU time and managed memory utilization of individual ASP.NET applications. As a result, with ASP.NET 4, administrators now have a more granular view into the resource consumption of individual applications running in a single worker process.

Multi-Targeting

You can create an application that targets a specific version of the .NET Framework. In ASP.NET 4, a new attribute in the *compilation* element of the `Web.config` file lets you target the .NET Framework 4 and later. If you explicitly target the .NET Framework 4, and if you include optional elements in the `Web.config` file such as the entries for *system.codedom*, these elements must be correct for the .NET Framework 4. (If you do not explicitly target the .NET Framework 4, the target framework is inferred from the lack of an entry in the `Web.config` file.)

The following example shows the use of the *targetFramework* attribute in the *compilation* element of the `Web.config` file.

```
<compilation targetFramework="4.0"/>
```

Note the following about targeting a specific version of the .NET Framework:

- In a .NET Framework 4 application pool, the ASP.NET build system assumes the .NET Framework 4 as a target if the `Web.config` file does not include the *targetFramework* attribute or if the `Web.config` file is missing. (You might have to make coding changes to your application to make it run under the .NET Framework 4.)
- If you do include the *targetFramework* attribute, and if the *system.codeDom* element is defined in the `Web.config` file, this file must contain the correct entries for the .NET Framework 4.
- If you are using the *aspnet_compiler* command to precompile your application (such as in a build environment), you must use the correct version of the *aspnet_compiler* command for the target framework. Use the compiler that shipped with the .NET Framework 2.0 (%WINDIR%\Microsoft.NET\Framework\v2.0.50727) to compile for the .NET Framework 3.5 and earlier versions. Use the compiler that ships with the .NET Framework 4 to compile applications created using that framework or using later versions.
- At run time, the compiler uses the latest framework assemblies that are installed on the computer (and therefore in the GAC). If an update is made later to the framework (for example, a hypothetical version 4.1 is

installed), you will be able to use features in the newer version of the framework even though the *targetFramework* attribute targets a lower version (such as 4.0). (However, at design time in Visual Studio 2010 or when you use the *aspnet_compiler* command, using newer features of the framework will cause compiler errors).

Ajax

jQuery Included with Web Forms and MVC

The Visual Studio templates for both Web Forms and MVC include the open-source jQuery library. When you create a new website or project, a Scripts folder containing the following 3 files is created:

- jQuery-1.4.1.js – The human-readable, unminified version of the jQuery library.
- jQuery-14.1.min.js – The minified version of the jQuery library.
- jQuery-1.4.1-vsdoc.js – The Intellisense documentation file for the jQuery library.

Include the unminified version of jQuery while developing an application. Include the minified version of jQuery for production applications.

For example, the following Web Forms page illustrates how you can use jQuery to change the background color of ASP.NET TextBox controls to yellow when they have focus.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="ShowjQuery.aspx.cs" Inherits="ShowjQuery" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">

<head runat="server">
    <title>Show jQuery</title>
</head>
<body>
    <form id="form1" runat="server">
    <div>

        <asp:TextBox ID="txtFirstName" runat="server" />
        <br />
        <asp:TextBox ID="txtLastName" runat="server" />
    </div>
    </form>
    <script src="Scripts/jquery-1.4.1.js" type="text/javascript"></script>

    <script type="text/javascript">

        $("input").focus( function() { $(this).css("background-color", "yellow"); });

    </script>
</body>
</html>
```

Content Delivery Network Support

The Microsoft Ajax Content Delivery Network (CDN) enables you to easily add ASP.NET Ajax and jQuery scripts to your Web applications. For example, you can start using the jQuery library simply by adding a `<script>` tag to your page that points to Ajax.microsoft.com like this:

```
<script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-1.4.2.js" type="text/javascript"></script>
```

By taking advantage of the Microsoft Ajax CDN, you can significantly improve the performance of your Ajax applications. The contents of the Microsoft Ajax CDN are cached on servers located around the world. In addition, the Microsoft Ajax CDN enables browsers to reuse cached JavaScript files for Web sites that are located in different

domains.

The Microsoft Ajax Content Delivery Network supports SSL (HTTPS) in case you need to serve a web page using the Secure Sockets Layer.

Implement a fallback when the CDN is unavailable. Test the fallback.

To learn more about the Microsoft Ajax CDN, visit the following website:

https://www.asp.net/ajaxlibrary/CDN.ashx

The ASP.NET ScriptManager supports the Microsoft Ajax CDN. Simply by setting one property, the EnableCdn property, you can retrieve all ASP.NET framework JavaScript files from the CDN:

```
<asp:ScriptManager ID="sm1" EnableCdn="true" runat="server" />
```

After you set the EnableCdn property to the value true, the ASP.NET framework will retrieve all ASP.NET framework JavaScript files from the CDN including all JavaScript files used for validation and the UpdatePanel. Setting this one property can have a dramatic impact on the performance of your web application.

You can set the CDN path for your own JavaScript files by using the WebResource attribute. The new CdnPath property specifies the path to the CDN used when you set the EnableCdn property to the value true:

```
[assembly: WebResource("Foo.js", "application/x-javascript", CdnPath = "http://foo.com/foo/bar/foo.js")]
```

ScriptManager Explicit Scripts

In the past, if you used the ASP.NET ScriptManger then you were required to load the entire monolithic ASP.NET Ajax Library. By taking advantage of the new ScriptManager.AjaxFrameworkMode property, you can control exactly which components of the ASP.NET Ajax Library are loaded and load only the components of the ASP.NET Ajax Library that you need.

The ScriptManager.AjaxFrameworkMode property can be set to the following values:

- Enabled -- Specifies that the ScriptManager control automatically includes the MicrosoftAjax.js script file, which is a combined script file of every core framework script (legacy behavior).
- Disabled -- Specifies that all Microsoft Ajax script features are disabled and that the ScriptManager control does not reference any scripts automatically.
- Explicit -- Specifies that you will explicitly include script references to individual framework core script file that your page requires, and that you will include references to the dependencies that each script file requires.

For example, if you set the AjaxFrameworkMode property to the value Explicit then you can specify the particular ASP.NET Ajax component scripts that you need:

```
<asp:ScriptManager ID="sm1" AjaxFrameworkMode="Explicit" runat="server">

<Scripts>
    <asp:ScriptReference Name="MicrosoftAjaxCore.js" />
    <asp:ScriptReference Name="MicrosoftAjaxComponentModel.js" />
    <asp:ScriptReference Name="MicrosoftAjaxSerialization.js" />
    <asp:ScriptReference Name="MicrosoftAjaxNetwork.js" />
</Scripts>
</asp:ScriptManager>
```

Web Forms

Web Forms has been a core feature in ASP.NET since the release of ASP.NET 1.0. Many enhancements have been in

this area for ASP.NET 4, including the following:

- The ability to set *meta* tags.
- More control over view state.
- Easier ways to work with browser capabilities.
- Support for using ASP.NET routing with Web Forms.
- More control over generated IDs.
- The ability to persist selected rows in data controls.
- More control over rendered HTML in the *FormView* and *ListView* controls.
- Filtering support for data source controls.

Setting Meta Tags with the Page.MetaKeywords and Page.MetaDescription Properties

ASP.NET 4 adds two properties to the *Page* class, *MetaKeywords* and *MetaDescription*. These two properties represent corresponding *meta* tags in your page, as shown in the following example:

```
<head id="Head1" runat="server">
  <title>Untitled Page</title>
  <meta name="keywords" content="These, are, my, keywords" />
  <meta name="description" content="This is the description of my page" />
</head>
```

These two properties work the same way that the page's *Title* property does. They follow these rules:

1. If there are no *meta* tags in the *head* element that match the property names (that is, name="keywords" for *Page.MetaKeywords* and name="description" for *Page.MetaDescription*, meaning that these properties have not been set), the *meta* tags will be added to the page when it is rendered.
2. If there are already *meta* tags with these names, these properties act as get and set methods for the contents of the existing tags.

You can set these properties at run time, which lets you get the content from a database or other source, and which lets you set the tags dynamically to describe what a particular page is for.

You can also set the *Keywords* and *Description* properties in the *@ Page* directive at the top of the Web Forms page markup, as in the following example:

```
<%@ Page Language="C#" AutoEventWireup="true"
  CodeFile="Default.aspx.cs"
  Inherits="_Default"
  Keywords="These, are, my, keywords"
  Description="This is a description" %>
```

This will override the *meta* tag contents (if any) already declared in the page.

The contents of the description *meta* tag are used for improving search listing previews in Google. (For details, see Improve snippets with a meta description makeover on the Google Webmaster Central blog.) Google and Windows Live Search do not use the contents of the keywords for anything, but other search engines might. For more information, see Meta Keywords Advice on the Search Engine Guide Web site.

These new properties are a simple feature, but they save you from the requirement to add these manually or from writing your own code to create the *meta* tags.

Enabling View State for Individual Controls

By default, view state is enabled for the page, with the result that each control on the page potentially stores view state even if it is not required for the application. View state data is included in the markup that a page generates and increases the amount of time it takes to send a page to the client and post it back. Storing more view state

than is necessary can cause significant performance degradation. In earlier versions of ASP.NET, developers could disable view state for individual controls in order to reduce page size, but had to do so explicitly for individual controls. In ASP.NET 4, Web server controls include a *ViewStateMode* property that lets you disable view state by default and then enable it only for the controls that require it in the page.

The *ViewStateMode* property takes an enumeration that has three values: *Enabled*, *Disabled*, and *Inherit*. *Enabled* enables view state for that control and for any child controls that are set to *Inherit* or that have nothing set. *Disabled* disables view state, and *Inherit* specifies that the control uses the *ViewStateMode* setting from the parent control.

The following example shows how the *ViewStateMode* property works. The markup and code for the controls in the following page includes values for the *ViewStateMode* property:

```
<form id="form1" runat="server">
  <script runat="server">
      protected override void OnLoad(EventArgs e) {
      if (!IsPostBack) {
        label1.Text = label2.Text = "[DynamicValue]";
      }
      base.OnLoad(e);
    }
  </script>
  <asp:PlaceHolder ID="PlaceHolder1" runat="server" ViewStateMode="Disabled">
      Disabled: <asp:Label ID="label1" runat="server" Text="[DeclaredValue]" /><br />
    <asp:PlaceHolder ID="PlaceHolder2" runat="server" ViewStateMode="Enabled">
        Enabled: <asp:Label ID="label2" runat="server" Text="[DeclaredValue]" />
    </asp:PlaceHolder>
  </asp:PlaceHolder>
  <hr />
  <asp:button ID="Button1" runat="server" Text="Postback" />
  <%-- Further markup here --%>
```

As you can see, the code disables view state for the PlaceHolder1 control. The child label1 control inherits this property value (*Inherit* is the default value for *ViewStateMode* for controls.) and therefore saves no view state. In the PlaceHolder2 control, *ViewStateMode* is set to *Enabled*, so label2 inherits this property and saves view state. When the page is first loaded, the *Text* property of both *Label* controls is set to the string "[DynamicValue]".

The effect of these settings is that when the page loads the first time, the following output is displayed in the browser:

Disabled `: [DynamicValue]`

Enabled: `[DynamicValue]`

After a postback, however, the following output is displayed:

Disabled `: [DeclaredValue]`

Enabled: `[DynamicValue]`

The label1 control (whose *ViewStateMode* value is set to *Disabled*) has not preserved the value that it was set to in code. However, the label2 control (whose *ViewStateMode* value is set to *Enabled*) has preserved its state.

You can also set *ViewStateMode* in the *@ Page* directive, as in the following example:

```
<%@ Page Language="C#" AutoEventWireup="true"
  CodeBehind="Default.aspx.cs"
  Inherits="WebApplication1._Default"
  ViewStateMode="Disabled" %>
```

The *Page* class is just another control; it acts as the parent control for all the other controls in the page. The default value of *ViewStateMode* is *Enabled* for instances of *Page*. Because controls default to *Inherit*, controls will inherit the *Enabled* property value unless you set *ViewStateMode* at page or control level.

The value of the *ViewStateMode* property determines if view state is maintained only if the *EnableViewState* property is set to *true*. If the *EnableViewState* property is set to *false*, view state will not be maintained even if *ViewStateMode* is set to *Enabled*.

A good use for this feature is with *ContentPlaceHolder* controls in master pages, where you can set *ViewStateMode* to *Disabled* for the master page and then enable it individually for *ContentPlaceHolder* controls that in turn contain controls that require view state.

Changes to Browser Capabilities

ASP.NET determines the capabilities of the browser that a user is using to browse your site by using a feature called *browser capabilities*. Browser capabilities are represented by the *HttpBrowserCapabilities* object (exposed by the *Request.Browser* property). For example, you can use the *HttpBrowserCapabilities* object to determine whether the type and version of the current browser supports a particular version of JavaScript. Or, you can use the *HttpBrowserCapabilities* object to determine whether the request originated from a mobile device.

The *HttpBrowserCapabilities* object is driven by a set of browser definition files. These files contain information about the capabilities of particular browsers. In ASP.NET 4, these browser definition files have been updated to contain information about recently introduced browsers and devices such as Google Chrome, Research in Motion BlackBerry smartphones, and Apple iPhone.

The following list shows new browser definition files:

- *blackberry.browser*
- *chrome.browser*
- *Default.browser*
- *firefox.browser*
- *gateway.browser*
- *generic.browser*
- *ie.browser*
- *iemobile.browser*
- *iphone.browser*
- *opera.browser*
- *safari.browser*

Using Browser Capabilities Providers

In ASP.NET version 3.5 Service Pack 1, you can define the capabilities that a browser has in the following ways:

- At the computer level, you create or update a `.browser` XML file in the following folder:

  ```
  \Windows\Microsoft.NET\Framework\v2.0.50727\CONFIG\Browsers
  ```

- After you define the browser capability, you run the following command from the Visual Studio Command Prompt in order to rebuild the browser capabilities assembly and add it to the GAC:

  ```
  aspnet_regbrowsers.exe -I c
  ```

- For an individual application, you create a `.browser` file in the application's `App_Browsers` folder.

These approaches require you to change XML files, and for computer-level changes, you must restart the

application after you run the aspnet_regbrowsers.exe process.

ASP.NET 4 includes a feature referred to as *browser capabilities providers*. As the name suggests, this lets you build a provider that in turn lets you use your own code to determine browser capabilities.

In practice, developers often do not define custom browser capabilities. Browser files are hard to update, the process for updating them is fairly complicated, and the XML syntax for `.browser` files can be complex to use and define. What would make this process much easier is if there were a common browser definition syntax, or a database that contained up-to-date browser definitions, or even a Web service for such a database. The new browser capabilities providers feature makes these scenarios possible and practical for third-party developers.

There are two main approaches for using the new ASP.NET 4 browser capabilities provider feature: extending the ASP.NET browser capabilities definition functionality, or totally replacing it. The following sections describe first how to replace the functionality, and then how to extend it.

Replacing the ASP.NET Browser Capabilities Functionality

To replace the ASP.NET browser capabilities definition functionality completely, follow these steps:

1. Create a provider class that derives from *HttpCapabilitiesProvider* and that overrides the *GetBrowserCapabilities* method, as in the following example:

   ```
   public class CustomProvider : HttpCapabilitiesProvider
   {
       public override HttpBrowserCapabilities
       GetBrowserCapabilities(HttpRequest request)
       {
           HttpBrowserCapabilities browserCaps = new HttpBrowserCapabilities();
           Hashtable values = new Hashtable(180, StringComparer.OrdinalIgnoreCase);
           values[String.Empty] = request.UserAgent;
           values["browser"] = "MyCustomBrowser";
           browserCaps.Capabilities = values;
           return browserCaps;
       }
   }
   ```

   The code in this example creates a new *HttpBrowserCapabilities* object, specifying only the capability named browser and setting that capability to MyCustomBrowser.

2. Register the provider with the application.

   In order to use a provider with an application, you must add the *provider* attribute to the *browserCaps* section in the `Web.config` or `Machine.config` files. (You can also define the provider attributes in a *location* element for specific directories in application, such as in a folder for a specific mobile device.) The following example shows how to set the *provider* attribute in a configuration file:

   ```
   <system.web>
   <browserCaps provider="ClassLibrary2.CustomProvider, ClassLibrary2,
     Version=1.0.0.0, Culture=neutral" />
   </system.web>
   ```

   Another way to register the new browser capability definition is to use code, as shown in the following example:

```
void Application_Start(object sender, EventArgs e)
{
    HttpCapabilitiesBase.BrowserCapabilitiesProvider =
    new ClassLibrary2.CustomProvider();
    // ...
 }
```

This code must run in the *Application_Start* event of the `Global.asax` file. Any change to the *BrowserCapabilitiesProvider* class must occur before any code in the application executes, in order to make sure that the cache remains in a valid state for the resolved *HttpCapabilitiesBase* object.

Caching the HttpBrowserCapabilities Object

The preceding example has one problem, which is that the code would run each time the custom provider is invoked in order to get the *HttpBrowserCapabilities* object. This can happen multiple times during each request. In the example, the code for the provider does not do much. However, if the code in your custom provider performs significant work in order to get the *HttpBrowserCapabilities* object, this can affect performance. To prevent this from happening, you can cache the *HttpBrowserCapabilities* object. Follow these steps:

1. Create a class that derives from *HttpCapabilitiesProvider*, like the one in the following example:

```
public class CustomProvider : HttpCapabilitiesProvider
{
    public override HttpBrowserCapabilities
    GetBrowserCapabilities(HttpRequest request)
    {
        string cacheKey = BuildCacheKey();
        int cacheTime = GetCacheTime();
        HttpBrowserCapabilities browserCaps =
        HttpContext.Current.Cache[cacheKey] as
        HttpBrowserCapabilities;
        if (browserCaps == null)
        {
            HttpBrowserCapabilities browserCaps = new
            HttpBrowserCapabilities();
            Hashtable values = new Hashtable(180,
            StringComparer.OrdinalIgnoreCase);
            values[String.Empty] = request.UserAgent;
            values["browser"] = "MyCustomBrowser";
            browserCaps.Capabilities = values;
            HttpContext.Current.Cache.Insert(cacheKey,
            browserCaps, null, DateTime.MaxValue,
            TimeSpan.FromSeconds(cacheTime));
        }
        return browserCaps;
    }
}
```

   In the example, the code generates a cache key by calling a custom BuildCacheKey method, and it gets the length of time to cache by calling a custom GetCacheTime method. The code then adds the resolved *HttpBrowserCapabilities* object to the cache. The object can be retrieved from the cache and reused on subsequent requests that make use of the custom provider.

2. Register the provider with the application as described in the preceding procedure.

Extending ASP.NET Browser Capabilities Functionality

The previous section described how to create a new *HttpBrowserCapabilities* object in ASP.NET 4. You can also extend the ASP.NET browser capabilities functionality by adding new browser capabilities definitions to those that are already in ASP.NET. You can do this without using the XML browser definitions. The following procedure shows how.

1. Create a class that derives from *HttpCapabilitiesEvaluator* and that overrides the *GetBrowserCapabilities* method, as shown in the following example:

```
public class CustomProvider : HttpCapabilitiesEvaluator
{
    public override HttpBrowserCapabilities
    GetBrowserCapabilities(HttpRequest request)
    {
        HttpBrowserCapabilities browserCaps =
        base.GetHttpBrowserCapabilities(request);
        if (browserCaps.Browser == "Unknown")
        {
            browserCaps = MyBrowserCapabilitiesEvaulator(request);
        }
        return browserCaps;
    }
}
```

   This code first uses the ASP.NET browser capabilities functionality to try to identify the browser. However, if no browser is identified based on the information defined in the request (that is, if the *Browser* property of the *HttpBrowserCapabilities* object is the string "Unknown"), the code calls the custom provider (MyBrowserCapabilitiesEvaluator) to identify the browser.

2. Register the provider with the application as described in the previous example.

Extending Browser Capabilities Functionality by Adding New Capabilities to Existing Capabilities Definitions

In addition to creating a custom browser definition provider and to dynamically creating new browser definitions, you can extend existing browser definitions with additional capabilities. This lets you use a definition that is close to what you want but lacks only a few capabilities. To do this, use the following steps.

1. Create a class that derives from *HttpCapabilitiesEvaluator* and that overrides the *GetBrowserCapabilities* method, as shown in the following example:

```
public class CustomProvider : HttpCapabilitiesEvaluator
{
    public override HttpBrowserCapabilities
    GetBrowserCapabilities(HttpRequest request)
    {
        HttpBrowserCapabilities browserCaps =
          base.GetHttpBrowserCapabilities(request);
        if (browserCaps.Browser == "Unknown")
        {
            browserCaps = MyBrowserCapabilitiesEvaulator(request);
        }
        return browserCaps;
    }
}
```

   The example code extends the existing ASP.NET *HttpCapabilitiesEvaluator* class and gets the *HttpBrowserCapabilities* object that matches the current request definition by using the following code:

```
HttpBrowserCapabilities browserCaps =
    base.GetHttpBrowserCapabilities(request);
```

   The code can then add or modify a capability for this browser. There are two ways to specify a new browser capability:

   - Add a key/value pair to the *IDictionary* object that is exposed by the *Capabilities* property of the *HttpCapabilitiesBase* object. In the previous example, the code adds a capability named MultiTouch

with a value of *true*.

- Set existing properties of the *HttpCapabilitiesBase* object. In the previous example, the code sets the *Frames* property to *true*. This property is simply an accessor for the *IDictionary* object that is exposed by the *Capabilities* property.

> **NOTE**
>
> Note This model applies to any property of *HttpBrowserCapabilities*, including control adapters.

2. Register the provider with the application as described in the earlier procedure.

Routing in ASP.NET 4

ASP.NET 4 adds built-in support for using routing with Web Forms. Routing lets you configure an application to accept request URLs that do not map to physical files. Instead, you can use routing to define URLs that are meaningful to users and that can help with search-engine optimization (SEO) for your application. For example, the URL for a page that displays product categories in an existing application might look like the following example:

```
http://website/products.aspx?categoryid=12
```

By using routing, you can configure the application to accept the following URL to render the same information:

```
http://website/products/software
```

Routing has been available starting with ASP.NET 3.5 SP1. (For an example of how to use routing in ASP.NET 3.5 SP1, see the entry Using Routing With WebForms on Phil Haack's blog.) However, ASP.NET 4 includes some features that make it easier to use routing, including the following:

- The *PageRouteHandler* class, which is a simple HTTP handler that you use when you define routes. The class passes data to the page that the request is routed to.
- The new properties *HttpRequest.RequestContext* and *Page.RouteData* (which is a proxy for the *HttpRequest.RequestContext.RouteData* object). These properties make it easier to access information that is passed from the route.
- The following new expression builders, which are defined in *System.Web.Compilation.RouteUrlExpressionBuilder* and *System.Web.Compilation.RouteValueExpressionBuilder*.
- *RouteUrl*, which provides a simple way to create a URL that corresponds to a route URL within an ASP.NET server control.
- *RouteValue*, which provides a simple way to extract information from the *RouteContext* object.
- The *RouteParameter* class, which makes it easier to pass data contained in a *RouteContext* object to a query for a data source control (similar to *FormParameter*).

Routing for Web Forms Pages

The following example shows how to define a Web Forms route by using the new *MapPageRoute* method of the *Route* class:

```
public class Global : System.Web.HttpApplication
{
    void Application_Start(object sender, EventArgs e)
    {
        RouteTable.Routes.MapPageRoute("SearchRoute",
          "search/{searchterm}", "~/search.aspx");
        RouteTable.Routes.MapPageRoute("UserRoute",
          "users/{username}", "~/users.aspx");
    }
}
```

ASP.NET 4 introduces the *MapPageRoute* method. The following example is equivalent to the SearchRoute definition shown in the previous example, but uses the *PageRouteHandler* class.

```
RouteTable.Routes.Add("SearchRoute", new Route("search/{searchterm}",
  new PageRouteHandler("~/search.aspx")));
```

The code in the example maps the route to a physical page (in the first route, to `~/search.aspx`). The first route definition also specifies that the parameter named searchterm should be extracted from the URL and passed to the page.

The *MapPageRoute* method supports the following method overloads:

- *MapPageRoute(string routeName, string routeUrl, string physicalFile, bool checkPhysicalUrlAccess)*
- *MapPageRoute(string routeName, string routeUrl, string physicalFile, bool checkPhysicalUrlAccess, RouteValueDictionary defaults)*
- *MapPageRoute(string routeName, string routeUrl, string physicalFile, bool checkPhysicalUrlAccess, RouteValueDictionary defaults, RouteValueDictionary constraints)*

The *checkPhysicalUrlAccess* parameter specifies whether the route should check the security permissions for the physical page being routed to (in this case, search.aspx) and the permissions on the incoming URL (in this case, search/{searchterm}). If the value of *checkPhysicalUrlAccess* is *false*, only the permissions of the incoming URL will be checked. These permissions are defined in the `Web.config` file using settings such as the following:

```
<configuration>
  <location path="search.aspx">
    <system.web>
      <authorization>
        <allow roles="admin"/>
        <deny users="*"/>
      </authorization>
    </system.web>
  </location>
  <location path="search">
    <system.web>
      <authorization>
        <allow users="*"/>
      </authorization>
    </system.web>
  </location>

</configuration>
```

In the example configuration, access is denied to the physical page `search.aspx` for all users except those who are in the admin role. When the *checkPhysicalUrlAccess* parameter is set to *true* (which is its default value), only admin users are allowed to access the URL /search/{searchterm}, because the physical page search.aspx is restricted to users in that role. If *checkPhysicalUrlAccess* is set to *false* and the site is configured as shown in the previous example, all authenticated users are allowed to access the URL /search/{searchterm}.

Reading Routing Information in a Web Forms Page

In the code of the Web Forms physical page, you can access the information that routing has extracted from the URL (or other information that another object has added to the *RouteData* object) by using two new properties: *HttpRequest.RequestContext* and *Page.RouteData*. (*Page.RouteData* wraps *HttpRequest.RequestContext.RouteData*.) The following example shows how to use *Page.RouteData*.

```
protected void Page_Load(object sender, EventArgs e)
{
    string searchterm = Page.RouteData.Values["searchterm"] as string;
    label1.Text = searchterm;
}
```

The code extracts the value that was passed for the searchterm parameter, as defined in the example route earlier. Consider the following request URL:

```
http://localhost/search/scott/
```

When this request is made, the word "scott" would be rendered in the `search.aspx` page.

Accessing Routing Information in Markup

The method described in the previous section shows how to get route data in code in a Web Forms page. You can also use expressions in markup that give you access to the same information. Expression builders are a powerful and elegant way to work with declarative code. (For more information, see the entry Express Yourself With Custom Expression Builders on Phil Haack's blog.)

ASP.NET 4 includes two new expression builders for Web Forms routing. The following example shows how to use them.

```
<asp:HyperLink ID="HyperLink1" runat="server"
  NavigateUrl="<%$RouteUrl:SearchTerm=scott%>">Search for Scott</asp:HyperLink>
```

In the example, the *RouteUrl* expression is used to define a URL that is based on a route parameter. This saves you from having to hard-code the complete URL into the markup, and lets you change the URL structure later without requiring any change to this link.

Based on the route defined earlier, this markup generates the following URL:

```
http://localhost/search/scott
```

ASP.NET automatically works out the correct route (that is, it generates the correct URL) based on the input parameters. You can also include a route name in the expression, which lets you specify a route to use.

The following example shows how to use the *RouteValue* expression.

```
<asp:Label ID="Label1" runat="server" Text="<%$RouteValue:SearchTerm%>" />
```

When the page that contains this control runs, the value "scott" is displayed in the label.

The *RouteValue* expression makes it simple to use route data in markup, and it avoids having to work with the more complex Page.RouteData["x"] syntax in markup.

Using Route Data for Data Source Control Parameters

The *RouteParameter* class lets you specify route data as a parameter value for queries in a data source control. It works much like the class, as shown in the following example:

```
<asp:sqldatasource id="SqlDataSource1" runat="server"
    connectionstring="<%$ ConnectionStrings:MyNorthwind %>"
    selectcommand="SELECT CompanyName,ShipperID FROM Shippers where
      CompanyName=@companyname"
  <selectparameters>
    <asp:routeparameter name="companyname" RouteKey="searchterm" />
  </selectparameters>

</asp:sqldatasource>
```

In this case, the value of the route parameter searchterm will be used for the @companyname parameter in the *Select* statement.

Setting Client IDs

The new *ClientIDMode* property addresses a long-standing issue in ASP.NET, namely how controls create the *id* attribute for elements that they render. Knowing the *id* attribute for rendered elements is important if your application includes client script that references these elements.

The *id* attribute in HTML that is rendered for Web server controls is generated based on the *ClientID* property of the control. Until ASP.NET 4, the algorithm for generating the *id* attribute from the *ClientID* property has been to concatenate the naming container (if any) with the ID, and in the case of repeated controls (as in data controls), to add a prefix and a sequential number. While this has always guaranteed that the IDs of controls in the page are unique, the algorithm has resulted in control IDs that were not predictable, and were therefore difficult to reference in client script.

The new *ClientIDMode* property lets you specify more precisely how the client ID is generated for controls. You can set the *ClientIDMode* property for any control, including for the page. Possible settings are the following:

- *AutoID* – This is equivalent to the algorithm for generating *ClientID* property values that was used in earlier versions of ASP.NET.
- *Static* – This specifies that the *ClientID* value will be the same as the ID without concatenating the IDs of parent naming containers. This can be useful in Web user controls. Because a Web user control can be located on different pages and in different container controls, it can be difficult to write client script for controls that use the *AutoID* algorithm because you cannot predict what the ID values will be.
- *Predictable* – This option is primarily for use in data controls that use repeating templates. It concatenates the ID properties of the control's naming containers, but generated *ClientID* values do not contain strings like "ctlxxx". This setting works in conjunction with the *ClientIDRowSuffix* property of the control. You set the *ClientIDRowSuffix* property to the name of a data field, and the value of that field is used as the suffix for the generated *ClientID* value. Typically you would use the primary key of a data record as the *ClientIDRowSuffix* value.
- *Inherit* – This setting is the default behavior for controls; it specifies that a control's ID generation is the same as its parent.

You can set the *ClientIDMode* property at the page level. This defines the default *ClientIDMode* value for all controls in the current page.

The default *ClientIDMode* value at the page level is *AutoID*, and the default *ClientIDMode* value at the control level is *Inherit*. As a result, if you do not set this property anywhere in your code, all controls will default to the *AutoID* algorithm.

You set the page-level value in the *@ Page* directive, as shown in the following example:

```
<%@ Page Language="C#" AutoEventWireup="true"
  CodeFile="Default.aspx.cs"
  Inherits="_Default"
  ClientIDMode="Predictable" %>
```

You can also set the *ClientIDMode* value in the configuration file, either at the computer (machine) level or at the application level. This defines the default *ClientIDMode* setting for all controls in all pages in the application. If you set the value at the computer level, it defines the default *ClientIDMode* setting for all Web sites on that computer. The following example shows the *ClientIDMode* setting in the configuration file:

```
<system.web>
  <pages clientIDMode="Predictable"></pages>
</system.web>
```

As noted earlier, the value of the *ClientID* property is derived from the naming container for a control's parent. In some scenarios, such as when you are using master pages, controls can end up with IDs like those in the following rendered HTML:

```
<div id="ctl00_ContentPlaceHolder1_ParentPanel">
  <div id="ctl00_ContentPlaceHolder1_ParentPanel_NamingPanel1">
    <input name="ctl00$ContentPlaceHolder1$ParentPanel$NamingPanel1$TextBox1"
      type="text" value="Hello!"
      id="ctl00_ContentPlaceHolder1_ParentPanel_NamingPanel1_TextBox1" />
</div>
```

Even though the *input* element shown in the markup (from a *TextBox* control) is only two naming containers deep in the page (the nested *ContentPlaceholder* controls), because of the way master pages are processed, the end result is a control ID like the following:

```
ctl00_ContentPlaceHolder1_ParentPanel_NamingPanel1_TextBox1
```

This ID is guaranteed to be unique in the page, but is unnecessarily long for most purposes. Imagine that you want to reduce the length of the rendered ID, and to have more control over how the ID is generated. (For example, you want to eliminate "ctlxxx" prefixes.) The easiest way to achieve this is by setting the *ClientIDMode* property as shown in the following example:

```
<tc:NamingPanel runat="server" ID="ParentPanel" ClientIDMode="Static">
  <tc:NamingPanel runat="server" ID="NamingPanel1" ClientIDMode="Predictable">
    <asp:TextBox ID="TextBox1" runat="server" Text="Hello!"></asp:TextBox>
  </tc:NamingPanel>

</tc:NamingPanel>
```

In this sample, the *ClientIDMode* property is set to *Static* for the outermost *NamingPanel* element, and set to *Predictable* for the inner *NamingControl* element. These settings result in the following markup (the rest of the page and the master page is assumed to be the same as in the previous example):

```
<div id="ParentPanel">
  <div id="ParentPanel_NamingPanel1">
    <input name="ctl00$ContentPlaceHolder1$ParentPanel$NamingPanel1$TextBox1"
        type="text" value="Hello!" id="ParentPanel_NamingPanel1_TextBox1" />
</div>
```

The *Static* setting has the effect of resetting the naming hierarchy for any controls inside the outermost

NamingPanel element, and of eliminating the *ContentPlaceHolder* and *MasterPage* IDs from the generated ID. (The *name* attribute of rendered elements is unaffected, so the normal ASP.NET functionality is retained for events, view state, and so on.) A side effect of resetting the naming hierarchy is that even if you move the markup for the *NamingPanel* elements to a different *ContentPlaceholder* control, the rendered client IDs remain the same.

> **NOTE**
>
> Note It is up to you to make sure that the rendered control IDs are unique. If they are not, it can break any functionality that requires unique IDs for individual HTML elements, such as the client *document.getElementById* function.

Creating Predictable Client IDs in Data-Bound Controls

The *ClientID* values that are generated for controls in a data-bound list control by the legacy algorithm can be long and are not really predictable. The *ClientIDMode* functionality can help you have more control over how these IDs are generated.

The markup in the following example includes a *ListView* control:

```
<asp:ListView ID="ListView1" runat="server" DataSourceID="SqlDataSource1"
    OnSelectedIndexChanged="ListView1_SelectedIndexChanged"
    ClientIDMode="Predictable"
    RowClientIDRowSuffix="ProductID">
</asp:ListView>
```

In the previous example, the *ClientIDMode* and *RowClientIDRowSuffix* properties are set in markup. The *ClientIDRowSuffix* property can be used only in data-bound controls, and its behavior differs depending on which control you are using. The differences are these:

- *GridView* control — You can specify the name of one or more columns in the data source, which are combined at run time to create the client IDs. For example, if you set *RowClientIDRowSuffix* to "ProductName, ProductId", control IDs for rendered elements will have a format like the following:

  ```
  rootPanel_GridView1_ProductNameLabel_Chai_1
  ```

- *ListView* control — You can specify a single column in the data source that is appended to the client ID. For example, if you set *ClientIDRowSuffix* to "ProductName", the rendered control IDs will have a format like the following:

  ```
  rootPanel_ListView1_ProductNameLabel_1
  ```

- In this case the trailing 1 is derived from the product ID of the current data item.
- *Repeater* control— This control does not support the *ClientIDRowSuffix* property. In a *Repeater* control, the index of the current row is used. When you use ClientIDMode="Predictable" with a *Repeater* control, client IDs are generated that have the following format:

  ```
  Repeater1_ProductNameLabel_0
  ```

- The trailing 0 is the index of the current row.

The *FormView* and *DetailsView* controls do not display multiple rows, so they do not support the *ClientIDRowSuffix* property.

Persisting Row Selection in Data Controls

The *GridView* and *ListView* controls can let users select a row. In previous versions of ASP.NET, selection has been based on the row index on the page. For example, if you select the third item on page 1 and then move to page 2, the third item on that page is selected.

Persisted selection was initially supported only in Dynamic Data projects in the .NET Framework 3.5 SP1. When this feature is enabled, the current selected item is based on the data key for the item. This means that if you select the third row on page 1 and move to page 2, nothing is selected on page 2. When you move back to page 1, the third row is still selected. Persisted selection is now supported for the *GridView* and *ListView* controls in all projects by using the *EnablePersistedSelection* property, as shown in the following example:

```
<asp:GridView id="GridView2" runat="server" EnablePersistedSelection="true">
</asp:GridView>
```

ASP.NET Chart Control

The ASP.NET *Chart* control expands the data-visualization offerings in the .NET Framework. Using the *Chart* control, you can create ASP.NET pages that have intuitive and visually compelling charts for complex statistical or financial analysis. The ASP.NET *Chart* control was introduced as an add-on to the .NET Framework version 3.5 SP1 release and is part of the .NET Framework 4 release.

The control includes the following features:

- 35 distinct chart types.
- An unlimited number of chart areas, titles, legends, and annotations.
- A wide variety of appearance settings for all chart elements.
- 3-D support for most chart types.
- Smart data labels that can automatically fit around data points.
- Strip lines, scale breaks, and logarithmic scaling.
- More than 50 financial and statistical formulas for data analysis and transformation.
- Simple binding and manipulation of chart data.
- Support for common data formats such as dates, times, and currency.
- Support for interactivity and event-driven customization, including client click events using Ajax.
- State management.
- Binary streaming.

The following figures show examples of financial charts that are produced by the ASP.NET Chart control.

Figure 2: ASP.NET Chart control examples

For more examples of how to use the ASP.NET Chart control, download the sample code on the Samples Environment for Microsoft Chart Controls page on the MSDN Web site. You can find more samples of community content at the Chart Control Forum.

Adding the Chart Control to an ASP.NET Page

The following example shows how to add a *Chart* control to an ASP.NET page by using markup. In the example, the *Chart* control produces a column chart for static data points.

```
<asp:Chart ID="Chart1" runat="server">
  <Series>
    <asp:Series Name="Series1" ChartType="Column">
      <Points>
        <asp:DataPoint AxisLabel="Product A" YValues="345"/>
        <asp:DataPoint AxisLabel="Product B" YValues="456"/>
        <asp:DataPoint AxisLabel="Product C" YValues="125"/>
        <asp:DataPoint AxisLabel="Product D" YValues="957"/> &

      lt;/Points>
    </asp:Series>
  </Series>
  <ChartAreas>
    <asp:ChartArea Name="ChartArea1">
      <AxisY IsLogarithmic="True" />
    </asp:ChartArea>
  </ChartAreas>
  <Legends>
    <asp:Legend Name="Legend1" Title="Product Sales" />
  </Legends>

</asp:Chart>
```

Using 3-D Charts

The *Chart* control contains a *ChartAreas* collection, which can contain *ChartArea* objects that define characteristics of chart areas. For example, to use 3-D for a chart area, use the *Area3DStyle* property as in the following example:

```
<asp:ChartArea Name="ChartArea1">
  <area3dstyle
      Rotation="10"
      Perspective="10"
      Enable3D="True"
      Inclination="15"
      IsRightAngleAxes="False"
      WallWidth="0"
      IsClustered="False" />

  <%-- Additional markup here --%>
</asp:ChartArea>
```

The figure below shows a 3-D chart with four series of the *Bar* chart type.

Figure 3: 3-D Bar Chart

Using Scale Breaks and Logarithmic Scales

Scale breaks and logarithmic scales are two additional ways to add sophistication to the chart. These features are specific to each axis in a chart area. For example, to use these features on the primary Y axis of a chart area, use the *AxisY.IsLogarithmic* and *ScaleBreakStyle* properties in a *ChartArea* object. The following snippet shows how to use scale breaks on the primary Y axis.

```
<asp:ChartArea Name="ChartArea1">

  <axisy>

    <ScaleBreakStyle
        BreakLineStyle="Wave"
        CollapsibleSpaceThreshold="40"
        Enabled="True" />
  </axisy>

<%-- Additional markup here --%>
</asp:ChartArea>
```

The figure below shows the Y axis with scale breaks enabled.

Figure 4: Scale Breaks

Filtering Data with the QueryExtender Control

A very common task for developers who create data-driven Web pages is to filter data. This traditionally has been performed by building *Where* clauses in data source controls. This approach can be complicated, and in some cases the *Where* syntax does not let you take advantage of the full functionality of the underlying database.

To make filtering easier, a new *QueryExtender* control has been added in ASP.NET 4. This control can be added to *EntityDataSource* or *LinqDataSource* controls in order to filter the data returned by these controls. Because the *QueryExtender* control relies on LINQ, the filter is applied on the database server before the data is sent to the page, which results in very efficient operations.

The *QueryExtender* control supports a variety of filter options. The following sections describe these options and provide examples of how to use them.

Search

For the search option, the *QueryExtender* control performs a search in specified fields. In the following example, the control uses the text that is entered in the TextBoxSearch control and searches for its contents in the `ProductName` and `Supplier.CompanyName` columns in the data that is returned from the *LinqDataSource* control.

```
<asp:LinqDataSource ID="dataSource" runat="server"> TableName="Products">
</asp:LinqDataSource>
<asp:QueryExtender TargetControlID="dataSource" runat="server">
  <asp:SearchExpression DataFields="ProductName, Supplier.CompanyName"
      SearchType="StartsWith">
    <asp:ControlParameter ControlID="TextBoxSearch" />
  </asp:SearchExpression>
</asp:QueryExtender>
```

Range

The range option is similar to the search option, but specifies a pair of values to define the range. In the following example, the *QueryExtender* control searches the `UnitPrice` column in the data returned from the *LinqDataSource* control. The range is read from the TextBoxFrom and TextBoxTo controls on the page.

```
<asp:LinqDataSource ID="dataSource" runat="server"> TableName="Products">
</asp:LinqDataSource>
<asp:QueryExtender TargetControlID="dataSource" runat="server">
  <asp:RangeExpression DataField="UnitPrice" MinType="Inclusive"
      MaxType="Inclusive">
    <asp:ControlParameter ControlID="TextBoxFrom" />
    <asp:ControlParameter ControlID="TexBoxTo" />
  </asp:RangeExpression>

</asp:QueryExtender>
```

PropertyExpression

The property expression option lets you define a comparison to a property value. If the expression evaluates to *true*, the data that is being examined is returned. In the following example, the *QueryExtender* control filters data by comparing the data in the `Discontinued` column to the value from the CheckBoxDiscontinued control on the page.

```
<asp:LinqDataSource ID="dataSource" runat="server" TableName="Products">
</asp:LinqDataSource>
<asp:QueryExtender TargetControlID="dataSource" runat="server">
   <asp:PropertyExpression>
      <asp:ControlParameter ControlID="CheckBoxDiscontinued" Name="Discontinued" />
   </asp:PropertyExpression>
</asp:QueryExtender>
```

CustomExpression

Finally, you can specify a custom expression to use with the *QueryExtender* control. This option lets you call a function in the page that defines custom filter logic. The following example shows how to declaratively specify a custom expression in the *QueryExtender* control.

```
<asp:LinqDataSource ID="dataSource" runat="server" TableName="Products">
</asp:LinqDataSource>
<asp:QueryExtender TargetControlID="dataSource" runat="server">
  <asp:CustomExpression OnQuerying="FilterProducts" />
</asp:QueryExtender>
```

The following example shows the custom function that is invoked by the *QueryExtender* control. In this case, instead of using a database query that includes a *Where* clause, the code uses a LINQ query to filter the data.

```
protected void FilterProducts(object sender, CustomExpressionEventArgs e)
{
    e.Query = from p in e.Query.Cast()
      where p.UnitPrice >= 10
      select p;
}
```

These examples show only one expression being used in the *QueryExtender* control at a time. However, you can include multiple expressions inside the *QueryExtender* control.

Html Encoded Code Expressions

Some ASP.NET sites (especially with ASP.NET MVC) rely heavily on using `<%=` `expression %>` syntax (often called "code nuggets") to write some text to the response. When you use code expressions, it is easy to forget to HTML-encode the text, If the text comes from user input, it can leave pages open to an XSS (Cross Site Scripting) attack.

ASP.NET 4 introduces the following new syntax for code expressions:

```
<%: expression %>
```

This syntax uses HTML encoding by default when writing to the response. This new expression effectively translates to the following:

```
<%= HttpUtility.HtmlEncode(expression) %>
```

For example, <%: Request["UserInput"] %> performs HTML encoding on the value of *Request["UserInput"]*.

The goal of this feature is to make it possible to replace all instances of the old syntax with the new syntax so that you are not forced to decide at every step which one to use. However, there are cases in which the text being output is meant to be HTML or is already encoded, in which case this could lead to double encoding.

For those cases, ASP.NET 4 introduces a new interface, *IHtmlString*, along with a concrete implementation, *HtmlString*. Instances of these types let you indicate that the return value is already properly encoded (or otherwise examined) for displaying as HTML, and that therefore the value should not be HTML-encoded again. For example, the following should not be (and is not) HTML encoded:

```
<%: new HtmlString("<strong>HTML that is not encoded</strong>") %>
```

ASP.NET MVC 2 helper methods have been updated to work with this new syntax so that they are not double encoded, but only when you are running ASP.NET 4. This new syntax does not work when you run an application using ASP.NET 3.5 SP1.

Keep in mind that this does not guarantee protection from XSS attacks. For example, HTML that uses attribute values that are not in quotation marks can contain user input that is still susceptible. Note that the output of ASP.NET controls and ASP.NET MVC helpers always includes attribute values in quotation marks, which is the recommended approach.

Likewise, this syntax does not perform JavaScript encoding, such as when you create a JavaScript string based on user input.

Project Template Changes

In earlier versions of ASP.NET, when you use Visual Studio to create a new Web Site project or Web Application project, the resulting projects contain only a Default.aspx page, a default `Web.config` file, and the `App_Data` folder, as shown in the following illustration:

Visual Studio also supports an Empty Web Site project type, which contains no files at all, as shown in the following figure:

The result is that for the beginner, there is very little guidance on how to build a production Web application. Therefore, ASP.NET 4 introduces three new templates, one for an empty Web application project, and one each for a Web Application and Web Site project.

Empty Web Application Template

As the name suggests, the Empty Web Application template is a stripped-down Web Application project. You select this project template from the Visual Studio New Project dialog box, as shown in the following figure:

(Click to view full-size image)

When you create an Empty ASP.NET Web Application, Visual Studio creates the following folder layout:

This is similar to the Empty Web Site layout from earlier versions of ASP.NET, with one exception. In Visual Studio 2010, Empty Web Application and Empty Web Site projects contain the following minimal `Web.config` file that contains information used by Visual Studio to identify the framework that the project is targeting:

```
<?xml version="1.0"?>
<configuration>
    <system.web>
        <compilation debug="true" targetFramework="4.0" />
    </system.web>
</configuration>
```

Without this *targetFramework* property, Visual Studio defaults to targeting the .NET Framework 2.0 in order to preserve compatibility when opening older applications.

Web Application and Web Site Project Templates

The other two new project templates that are shipped with Visual Studio 2010 contain major changes. The following figure shows the project layout that is created when you create a new Web Application project. (The layout for a Web Site project is virtually identical.)

The project includes a number of files that were not created in earlier versions. In addition, the new Web Application project is configured with basic membership functionality, which lets you quickly get started in securing access to the new application. Because of this inclusion, the `Web.config` file for the new project includes entries that are used to configure membership, roles, and profiles. The following example shows the `Web.config` file for a new Web Application project. (In this case, *roleManager* is disabled.)

```
<?xml version="1.0"?>
<configuration>
    <connectionStrings>
      <add name="ApplicationServices" connectionString="data source=.\SQLEXPRESS;Integrated Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User
Instance=true" providerName="System.Data.SqlClient"/>
    </connectionStrings>

    <system.web>
      <compilation debug="true" targetFramework="4.0" />

      <authentication mode="Forms">
        <forms loginUrl="~/Account/Login.aspx"/>
      </authentication>

      <membership>
        <providers>
          <clear/>
          <add name="AspNetSqlMembershipProvider" type="System.Web.Security.SqlMembershipProvider, System.Web, Version=4.0.0.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a" connectionStringName="ApplicationServices" enablePasswordRetrieval="false" enablePasswordReset="true"
requiresQuestionAndAnswer="false" requiresUniqueEmail="false" passwordFormat="Hashed" maxInvalidPasswordAttempts="5" minRequiredPasswordLength="6"
minRequiredNonalphanumericCharacters="0" passwordAttemptWindow="10" passwordStrengthRegularExpression="" applicationName="/"/>
        </providers>
      </membership>

      <profile>
        <providers>
          <clear/>
          <add name="AspNetSqlProfileProvider" type="System.Web.Profile.SqlProfileProvider, System.Web, Version=4.0.0.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a" connectionStringName="ApplicationServices" applicationName="/"/>
        </providers>
      </profile>

      <roleManager enabled="false">
        <providers>
          <clear/>
          <add connectionStringName="ApplicationServices" applicationName="/" name="AspNetSqlRoleProvider" type="System.Web.Security.SqlRoleProvider,
System.Web, Version=4.0.0.0, Culture=neutral, PublicKeyToken=b03f5f7f11d50a3a"/>
          <add applicationName="/" name="AspNetWindowsTokenRoleProvider" type="System.Web.Security.WindowsTokenRoleProvider, System.Web, Version=4.0.0.0,
Culture=neutral, PublicKeyToken=b03f5f7f11d50a3a"/>
        </providers>
      </roleManager>

      <pages clientIDMode="Predictable">
      </pages>
    </system.web>
</configuration>
```

(Click to view full-size image)

The project also contains a second `Web.config` file in the `Account` directory. The second configuration file provides a way to secure access to the ChangePassword.aspx page for non-logged in users. The following example shows the contents of the second `Web.config` file.

```
<?xml version="1.0"?>
<configuration>
    <location path="ChangePassword.aspx">
      <system.web>
        <authorization>
          <deny users="?"/>
        </authorization>
      </system.web>
    </location>
</configuration>
```

The pages created by default in the new project templates also contain more content than in previous versions. The project contains a default master page and CSS file, and the default page (Default.aspx) is configured to use the master page by default. The result is that when you run the Web application or Web site for the first time, the default (home) page is already functional. In fact, it is similar to the default page you see when you start up a new MVC application.

(Click to view full-size image)

The intention of these changes to the project templates is to provide guidance on how to start building a new Web application. With semantically correct, strict XHTML 1.0-compliant markup and with layout that is specified using CSS, the pages in the templates represent best practices for building ASP.NET 4 Web applications. The default pages also have a two-column layout that you can easily customize.

For example, imagine that for a new Web Application you want to change some of the colors and insert your company logo in place of the My ASP.NET Application logo. To do this, you create a new directory under `Content` to store your logo image:

To add the image to the page, you then open the `Site.Master` file, find where the My ASP.NET Application text is defined, and replace it with an *image* element whose *src* attribute is set to the new logo image, as in the following example:

```
<div class="title">
    <img src="Content/Images/ASPNETLogo.jpg" width="376px" height="62px" border="0" alt="ASP.NET Logo" />
</div>
```

(Click to view full-size image)

You can then go into the Site.css file and modify CSS class definitions to change the background color of the page as well as that of the header.

The result of these changes is that you can display a customized home page with very little effort:

(Click to view full-size image)

CSS Improvements

One of the major areas of work in ASP.NET 4 has been to help render HTML that is compliant with the latest HTML standards. This includes changes to how ASP.NET Web server controls use CSS styles.

Compatibility Setting for Rendering

By default, when a Web application or Web site targets the .NET Framework 4, the *controlRenderingCompatibilityVersion* attribute of the *pages* element is set to "4.0". This element is defined in the machine-level `Web.config` file and by default applies to all ASP.NET 4 applications:

```
<system.web>
  <pages controlRenderingCompatibilityVersion="3.5|4.0"/>
</system.web>
```

The value for *controlRenderingCompatibility* is a string, which allows potential new version definitions in future releases. In the current release, the following values are supported for this property:

- "3.5". This setting indicates legacy rendering and markup. Markup rendered by controls is 100% backward compatible, and the setting of the *xhtmlConformance* property is honored.
- "4.0". If the property has this setting, ASP.NET Web server controls do the following:
- The *xhtmlConformance* property is always treated as "Strict". As a result, controls render XHTML 1.0 Strict markup.
- Disabling non-input controls no longer renders invalid styles.
- *div* elements around hidden fields are now styled so they do not interfere with user-created CSS rules.
- Menu controls render markup that is semantically correct and compliant with accessibility guidelines.
- Validation controls do not render inline styles.
- Controls that previously rendered border="0" (controls that derive from the ASP.NET *Table* control, and the ASP.NET *Image* control) no longer render this attribute.

Disabling Controls

In ASP.NET 3.5 SP1 and earlier versions, the framework renders the *disabled* attribute in the HTML markup for any control whose *Enabled* property set to *false*. However, according to the HTML 4.01 specification, only *input* elements should have this attribute.

In ASP.NET 4, you can set the *controlRenderingCompatibilityVersion* property to "3.5", as in the following example:

```
<system.web>
  <pages controlRenderingCompatibilityVersion="3.5"/>
</system.web>
```

You might create markup for a *Label* control like the following, which disables the control:

```
<asp:Label id="Label" runat="server" Text="Test" Enabled="false">
```

The *Label* control would render the following HTML:

```
<span id="Label1" disabled="disabled">Test</span>
```

In ASP.NET 4, you can set the *controlRenderingCompatibilityVersion* to "4.0". In that case, only controls that render *input* elements will render a *disabled* attribute when the control's *Enabled* property is set to *false*. Controls that do not render HTML *input* elements instead render a *class* attribute that references a CSS class that you can use to define a disabled look for the control. For example, the *Label* control shown in the earlier example would generate

the following markup:

```
<span id="Span1" class="aspnetdisabled">Test</span>
```

The default value for the class that specified for this control is "aspNetDisabled". However, you can change this default value by setting the static *DisabledCssClass* static property of the *WebControl* class. For control developers, the behavior to use for a specific control can also be defined using the *SupportsDisabledAttribute* property.

Hiding div Elements Around Hidden Fields

ASP.NET 2.0 and later versions render system-specific hidden fields (such as the *hidden* element used to store view state information) inside *div* element in order to comply with the XHTML standard. However, this can cause a problem when a CSS rule affects *div* elements on a page. For example, it can result in a one-pixel line appearing in the page around hidden *div* elements. In ASP.NET 4, *div* elements that enclose the hidden fields generated by ASP.NET add a CSS class reference as in the following example:

```
<div class="aspNetHidden">...</div>
```

You can then define a CSS class that applies only to the *hidden* elements that are generated by ASP.NET, as in the following example:

```
<style type="text/css">
  DIV# aspNetHidden {border:0;}

</style>
```

Rendering an Outer Table for Templated Controls

By default, the following ASP.NET Web server controls that support templates are automatically wrapped in an outer table that is used to apply inline styles:

- *FormView*
- *Login*
- *PasswordRecovery*
- *ChangePassword*
- *Wizard*
- *CreateUserWizard*

A new property named *RenderOuterTable* has been added to these controls that allows the outer table to be removed from the markup. For example, consider the following example of a *FormView* control:

```
<asp:FormView ID="FormView1" runat="server">
  <ItemTemplate>
      Content
  </ItemTemplate>

</asp:FormView>
```

This markup renders the following output to the page, which includes an HTML table:

```
<table cellspacing="0" border="0" id="Table1" style="border-collapse:collapse;">
  <tr>
    <td colspan="2">
      Content
    </td>
  </tr>

</table>
```

To prevent the table from being rendered, you can set the *FormView* control's *RenderOuterTable* property, as in the following example:

```
<asp:FormView ID="FormView1" runat="server" RenderOuterTable="false">
```

The previous example renders the following output, without the *table*, *tr*, and *td* elements:

```
Content
```

This enhancement can make it easier to style the content of the control with CSS, because no unexpected tags are rendered by the control.

> **NOTE**
>
> Note This change disables support for the auto-format function in the Visual Studio 2010 designer, because there is no longer a *table* element that can host style attributes that are generated by the auto-format option.

ListView Control Enhancements

The *ListView* control has been made easier to use in ASP.NET 4. The earlier version of the control required that you specify a layout template that contained a server control with a known ID. The following markup shows a typical example of how to use the *ListView* control in ASP.NET 3.5.

```
<asp:ListView ID="ListView1" runat="server">
  <LayoutTemplate>
    <asp:PlaceHolder ID="ItemPlaceHolder" runat="server"></asp:PlaceHolder>
  </LayoutTemplate>
  <ItemTemplate>
    <% Eval("LastName")%>
  </ItemTemplate>
</asp:ListView>
```

In ASP.NET 4, the *ListView* control does not require a layout template. The markup shown in the previous example can be replaced with the following markup:

```
<asp:ListView ID="ListView1" runat="server">
  <ItemTemplate>
    <% Eval("LastName")%>
  </ItemTemplate>

</asp:ListView>
```

CheckBoxList and RadioButtonList Control Enhancements

In ASP.NET 3.5, you can specify layout for the *CheckBoxList* and *RadioButtonList* using the following two settings:

- *Flow*. The control renders *span* elements to contain its content.

- *Table*. The control renders a *table* element to contain its content.

The following example shows markup for each of these controls.

```
<asp:CheckBoxList ID="CheckBoxList1" runat="server" RepeatLayout="Flow">
  <asp:ListItem Text="CheckBoxList" Value="cbl" />
</asp:CheckBoxList>

<asp:RadioButtonList runat="server" RepeatLayout="Table">
  <asp:ListItem Text="RadioButtonList" Value="rbl" />
</asp:RadioButtonList>
```

By default, the controls render HTML similar to the following:

```
<span id="Span2"><input id="CheckBoxList1_0" type="checkbox"
    name="CheckBoxList1$0" /><label for="CheckBoxList1_0">CheckBoxList</label></span>

<table id="RadioButtonList1" border="0">
  <tr>
    <td><input id="RadioButtonList1_0" type="radio" name="RadioButtonList1" value="rbl" /><label
for="RadioButtonList1_0">RadioButtonList</label></td>
  </tr>

</table>
```

Because these controls contain lists of items, to render semantically correct HTML, they should render their contents using HTML list (*li*) elements. This makes it easier for users who read Web pages using assistive technology, and makes the controls easier to style using CSS.

In ASP.NET 4, the *CheckBoxList* and *RadioButtonList* controls support the following new values for the *RepeatLayout* property:

- *OrderedList* – The content is rendered as *li* elements within an *ol* element.
- *UnorderedList* – The content is rendered as *li* elements within a *ul* element.

The following example shows how to use these new values.

```
<asp:CheckBoxList ID="CheckBoxList1" runat="server"
      RepeatLayout="OrderedList">
  <asp:ListItem Text="CheckBoxList" Value="cbl" />
</asp:CheckBoxList>

<asp:RadioButtonList ID="RadioButtonList1" runat="server"
      RepeatLayout="UnorderedList">
  <asp:ListItem Text="RadioButtonList" Value="rbl" />
</asp:RadioButtonList>
```

The preceding markup generates the following HTML:

```
<ol id="CheckBoxList1">

  <li><input id="CheckBoxList1_0" type="checkbox" name="CheckBoxList1$0" value="cbl" /><label
for="CheckBoxList1_0">CheckBoxList</label></li>
</ol>

<ul id="RadioButtonList1">
  <li><input id="RadioButtonList1_0" type="radio" name="RadioButtonList1" value="rbl" /><label
for="RadioButtonList1_0">RadioButtonList</label></li>

</ul>
```

NOTE

Note If you set *RepeatLayout* to *OrderedList* or *UnorderedList*, the *RepeatDirection* property can no longer be used and will throw an exception at run time if the property has been set within your markup or code. The property would have no value because the visual layout of these controls is defined using CSS instead.

Menu Control Improvements

Before ASP.NET 4, the *Menu* control rendered a series of HTML tables. This made it more difficult to apply CSS styles outside of setting inline properties and was also not compliant with accessibility standards.

In ASP.NET 4, the control now renders HTML using semantic markup that consists of an unordered list and list elements. The following example shows markup in an ASP.NET page for the *Menu* control.

```
<asp:Menu ID="Menu1" runat="server">
  <Items> <asp:MenuItem Text="Home" Value="Home" />
    <asp:MenuItem Text="About" Value="About" />
  </Items>

</asp:Menu>
```

When the page renders, the control produces the following HTML (the *onclick* code has been omitted for clarity):

```
<div id="Menu1">
  <ul>
    <li><a href="#" onclick="...">Home</a></li>
    <li><a href="#" onclick="...">About</a></li>
  </ul>

</div>
<script type="text/javascript">
  new Sys.WebForms.Menu('Menu1');
</script>
```

In addition to rendering improvements, keyboard navigation of the menu has been improved using focus management. When the *Menu* control gets focus, you can use the arrow keys to navigate elements. The *Menu* control also now attaches accessible rich internet applications (ARIA) roles and attributes following thefor improved accessibility.

Styles for the menu control are rendered in a style block at the top of the page, rather than in line with the rendered HTML elements. If you want to take full control over the styling for the control, you can set the new *IncludeStyleBlock* property to *false*, in which case the style block is not emitted. One way to use this property is to use the auto-format feature in the Visual Studio designer to set the appearance of the menu. You can then run the page, open the page source, and then copy the rendered style block to an external CSS file. In Visual Studio, undo the styling and set *IncludeStyleBlock* to *false*. The result is that the menu appearance is defined using styles in an

external style sheet.

Wizard and CreateUserWizard Controls

The ASP.NET *Wizard* and *CreateUserWizard* controls support templates that let you define the HTML that they render. (*CreateUserWizard* derives from *Wizard*.) The following example shows the markup for a fully templated *CreateUserWizard* control:

```
<asp:CreateUserWizard ID="CreateUserWizard1" runat="server" ActiveStepIndex="0">
  <HeaderTemplate>
  </HeaderTemplate>

  <SideBarTemplate>
  </SideBarTemplate>

  <StepNavigationTemplate>
  </StepNavigationTemplate>

  <StartNavigationTemplate>
  </StartNavigationTemplate>

  <FinishNavigationTemplate>
  </FinishNavigationTemplate>

  <WizardSteps>
    <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
      <ContentTemplate>
      </ContentTemplate>

      <CustomNavigationTemplate>
      </CustomNavigationTemplate>

    </asp:CreateUserWizardStep>

    <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
      <ContentTemplate>
      </ContentTemplate>
    </asp:CompleteWizardStep>

  </WizardSteps>

</asp:CreateUserWizard>
```

The control renders HTML similar to the following:

```
<table cellspacing="0" cellpadding="0" border="0" id="CreateUserWizard1" style="border-collapse:collapse;">
  <tr>
    <td>Header</td>
  </tr>
  <tr style="height:100%;">
    <td>
      <table cellspacing="0" cellpadding="0" border="0" style="height:100%;width:100%;border-
collapse:collapse;">
        <tr>
          <td style="height:100%;width:100%;"></td>
        </tr>
      </table>
    </td>
  </tr>
  <tr>
    <td align="right"></td>
  </tr>

</table>
```

In ASP.NET 3.5 SP1, although you can change the template contents, you still have limited control over the output of the *Wizard* control. In ASP.NET 4, you can create a *LayoutTemplate* template and insert *PlaceHolder* controls (using reserved names) to specify how you want the *Wizard control* to render. The following example shows this:

```
<asp:CreateUserWizard ID="CreateUserWizard1" runat="server" ActiveStepIndex="1">
  <LayoutTemplate>
    <asp:PlaceHolder ID="headerPlaceholder" runat="server" />
    <asp:PlaceHolder ID="sideBarPlaceholder" runat="server" />
    <asp:PlaceHolder id="wizardStepPlaceholder" runat="server" />
    <asp:PlaceHolder id="navigationPlaceholder" runat="server" />
  </LayoutTemplate>
  <HeaderTemplate>
    Header
  </HeaderTemplate>
  <WizardSteps>
    <asp:CreateUserWizardStep runat="server">
      <ContentTemplate>
      </ContentTemplate>
    </asp:CreateUserWizardStep>
    <asp:CompleteWizardStep runat="server">
      <ContentTemplate>
      </ContentTemplate>
    </asp:CreateUserWizardStep>
  </WizardSteps>

</asp:CreateUserWizard>
```

The example contains the following named placeholders in the *LayoutTemplate* element:

- *headerPlaceholder* – At run time, this is replaced by the contents of the *HeaderTemplate* element.
- *sideBarPlaceholder* – At run time, this is replaced by the contents of the *SideBarTemplate* element.
- *wizardStepPlaceHolder* – At run time, this is replaced by the contents of the *WizardStepTemplate* element.
- *navigationPlaceholder* – At run time, this is replaced by any navigation templates that you have defined.

The markup in the example that uses placeholders renders the following HTML (without the content actually defined in the templates):

```
<span>
</span>
```

The only HTML that is now not user-defined is a *span* element. (We anticipate that in future releases, even the *span* element will not be rendered.) This now gives you full control over virtually all the content that is generated by the *Wizard* control.

ASP.NET MVC

ASP.NET MVC was introduced as an add-on framework to ASP.NET 3.5 SP1 in March 2009. Visual Studio 2010 includes ASP.NET MVC 2, which includes new features and capabilities.

Areas Support

Areas let you group controllers and views into sections of a large application in relative isolation from other sections. Each area can be implemented as a separate ASP.NET MVC project that can then be referenced by the main application. This helps manage complexity when you build a large application and makes it easier for multiple teams to work together on a single application.

Data-Annotation Attribute Validation Support

DataAnnotations attributes let you attach validation logic to a model by using metadata attributes. *DataAnnotations* attributes were introduced in ASP.NET Dynamic Data in ASP.NET 3.5 SP1. These attributes have

been integrated into the default model binder and provide a metadata-driven means to validate user input.

Templated Helpers

Templated helpers let you automatically associate edit and display templates with data types. For example, you can use a template helper to specify that a date-picker UI element is automatically rendered for a *System.DateTime* value. This is similar to field templates in ASP.NET Dynamic Data.

The *Html.EditorFor* and *Html.DisplayFor* helper methods have built-in support for rendering standard data types as well as complex objects with multiple properties. They also customize rendering by letting you apply data-annotation attributes like *DisplayName* and *ScaffoldColumn* to the *ViewModel* object.

Often you want to customize the output from UI helpers even further and have complete control over what is generated. The *Html.EditorFor* and *Html.DisplayFor* helper methods support this using a templating mechanism that lets you define external templates that can override and control the output rendered. The templates can be rendered individually for a class.

Dynamic Data

Dynamic Data was introduced in the .NET Framework 3.5 SP1 release in mid-2008. This feature provides many enhancements for creating data-driven applications, including the following:

- A RAD experience for quickly building a data-driven Web site.
- Automatic validation that is based on constraints defined in the data model.
- The ability to easily change the markup that is generated for fields in the *GridView* and *DetailsView* controls by using field templates that are part of your Dynamic Data project.

> **NOTE**
>
> Note For more information, see the Dynamic Data documentation in the MSDN Library.

For ASP.NET 4, Dynamic Data has been enhanced to give developers even more power for quickly building data-driven Web sites.

Enabling Dynamic Data for Existing Projects

Dynamic Data features that shipped in the .NET Framework 3.5 SP1 brought new features such as the following:

- Field templates – These provide data-type-based templates for data-bound controls. Field templates provide a simpler way to customize the look of data controls than using template fields for each field.
- Validation – Dynamic Data lets you use attributes on data classes to specify validation for common scenarios like required fields, range checking, type checking, pattern matching using regular expressions, and custom validation. Validation is enforced by the data controls.

However, these features had the following requirements:

- The data-access layer had to be based on Entity Framework or LINQ to SQL.
- The only data source controls supported for these features were the *EntityDataSource* or *LinqDataSource* controls.
- The features required a Web project that had been created using the Dynamic Data or Dynamic Data Entities templates in order to have all the files that were required to support the feature.

A major goal of Dynamic Data support in ASP.NET 4 is to enable the new functionality of Dynamic Data for any ASP.NET application. The following example shows markup for controls that can take advantage of Dynamic Data functionality in an existing page.

```
<asp:GridView ID="GridView1" runat="server" AutoGenerateColumns="True"
    DataKeyNames="ProductID" DataSourceID="LinqDataSource1">
</asp:GridView>
<asp:LinqDataSource ID="LinqDataSource1" runat="server"
    ContextTypeName="DataClassesDataContext" EnableDelete="True" EnableInsert="True"
    EnableUpdate="True" TableName="Products">

</asp:LinqDataSource>
```

In the code for the page, the following code must be added in order to enable Dynamic Data support for these controls:

```
GridView1.EnableDynamicData(typeof(Product));
```

When the *GridView* control is in edit mode, Dynamic Data automatically validates that the data entered is in the proper format. If it is not, an error message is displayed.

This functionality also provides other benefits, such as being able to specify default values for insert mode. Without Dynamic Data, to implement a default value for a field, you must attach to an event, locate the control (using *FindControl*), and set its value. In ASP.NET 4, the *EnableDynamicData* call supports a second parameter that lets you pass default values for any field on the object, as shown in this example:

```
DetailsView1.EnableDynamicData(typeof(Product), new { ProductName = "DefaultName" });
```

Declarative DynamicDataManager Control Syntax

The *DynamicDataManager* control has been enhanced so that you can configure it declaratively, as with most controls in ASP.NET, instead of only in code. The markup for the *DynamicDataManager* control looks like the following example:

```
<asp:DynamicDataManager ID="DynamicDataManager1" runat="server"
    AutoLoadForeignKeys="true">
  <DataControls>
    <asp:DataControlReference ControlID="GridView1" />
  </DataControls>

</asp:DynamicDataManager>
<asp:GridView id="GridView1" runat="server"
</asp:GridView>
```

This markup enables Dynamic Data behavior for the GridView1 control that is referenced in the *DataControls* section of the *DynamicDataManager* control.

Entity Templates

Entity templates offer a new way to customize the layout of data without requiring you to create a custom page. Page templates use the *FormView* control (instead of the *DetailsView* control, as used in page templates in earlier versions of Dynamic Data) and the *DynamicEntity* control to render Entity templates. This gives you more control over the markup that is rendered by Dynamic Data.

The following list shows the new project directory layout that contains entity templates:

```
\DynamicData\EntityTemplates
\DynamicData\EntityTemplates\Default.ascx
\DynamicData\EntityTemplates\Default_Edit.ascx
\DynamicData\EntityTemplates\Default_Insert.ascx
```

The `EntityTemplate` directory contains templates for how to display data model objects. By default, objects are rendered by using the `Default.ascx` template, which provides markup that looks just like the markup created by the *DetailsView* control used by Dynamic Data in ASP.NET 3.5 SP1. The following example shows the markup for the `Default.ascx` control:

```
<asp:EntityTemplate runat="server" ID="TemplateContainer1">
  <ItemTemplate>
    <tr
      <td>
        <asp:Label ID="Label1" runat="server" OnInit="Label_Init" />
      </td>
      <td>
        <asp:DynamicControl runat="server" OnInit="DynamicControl_Init" />
      </td>
    </tr>
  </ItemTemplate>

</asp:EntityTemplate>
```

The default templates can be edited to change the look and feel for the entire site. There are templates for display, edit, and insert operations. New templates can be added based on the name of the data object in order to change the look and feel of just one type of object. For example, you can add the following template:

```
\DynamicData\EntityTemplates\Products.aspx
```

The template might contain the following markup:

```
<tr>
  <td>Name</td>
  <td><asp:DynamicControl runat="server" DataField="ProductName" /></td>
  <td>Category</td>
  <td><asp:DynamicControl runat="server" DataField="Category" /></td>

</tr>
```

The new entity templates are displayed on a page by using the new *DynamicEntity* control. At run time, this control is replaced with the contents of the entity template. The following markup shows the *FormView* control in the `Detail.aspx` page template that uses the entity template. Notice the *DynamicEntity* element in the markup.

```
<asp:FormView runat="server" ID="FormView1"
    DataSourceID="DetailsDataSource"
    OnItemDeleted="FormView1_ItemDeleted">
  <ItemTemplate>
    <table class="DDDetailsTable" cellpadding="6">
      <asp:DynamicEntity runat="server" />
      <tr class="td">
        <td colspan="2">
          <asp:DynamicHyperLink ID="EditHyperLink" runat="server"
              Action="Edit" Text="Edit" />
          <asp:LinkButton ID="DeleteLinkButton" runat="server"
              CommandName="Delete"
              CausesValidation="false"
              OnClientClick='return confirm("Are you sure you want to delete this item?");'
              Text="Delete" />
        </td>
      </tr>
    </table>
  </ItemTemplate>

</asp:FormView>
```

New Field Templates for URLs and Email Addresses

ASP.NET 4 introduces two new built-in field templates, `EmailAddress.ascx` and `Url.ascx`. These templates are used for fields that are marked as *EmailAddress* or *Url* with the *DataType* attribute. For *EmailAddress* objects, the field is displayed as a hyperlink that is created by using the *mailto:* protocol. When users click the link, it opens the user's email client and creates a skeleton message. Objects typed as *Url* are displayed as ordinary hyperlinks.

The following example shows how fields would be marked.

```
[DataType(DataType.EmailAddress)]
public object HomeEmail { get; set; }

[DataType(DataType.Url)]
public object Website { get; set; }
```

Creating Links with the DynamicHyperLink Control

Dynamic Data uses the new routing feature that was added in the .NET Framework 3.5 SP1 to control the URLs that end users see when they access the Web site. The new *DynamicHyperLink* control makes it easy to build links to pages in a Dynamic Data site. The following example shows how to use the *DynamicHyperLink* control:

```
<asp:DynamicHyperLink ID="ListHyperLink" runat="server"
    Action="List" TableName="Products">
    Show all products
</asp:DynamicHyperLink>
```

This markup creates a link that points to the List page for the `Products` table based on routes that are defined in the `Global.asax` file. The control automatically uses the default table name that the Dynamic Data page is based on.

Support for Inheritance in the Data Model

Both the Entity Framework and LINQ to SQL support inheritance in their data models. An example of this might be a database that has an `InsurancePolicy` table. It might also contain `CarPolicy` and `HousePolicy` tables that have the same fields as `InsurancePolicy` and then add more fields. Dynamic Data has been modified to understand inherited objects in the data model and to support scaffolding for the inherited tables.

Support for Many-to-Many Relationships (Entity Framework Only)

The Entity Framework has rich support for many-to-many relationships between tables, which is implemented by exposing the relationship as a collection on an *Entity* object. New `ManyToMany.ascx` and `ManyToMany_Edit.ascx` field templates have been added to provide support for displaying and editing data that is involved in many-to-many relationships.

New Attributes to Control Display and Support Enumerations

The *DisplayAttribute* has been added to give you additional control over how fields are displayed. The *DisplayName* attribute in earlier versions of Dynamic Data allowed you to change the name that is used as a caption for a field. The new *DisplayAttribute* class lets you specify more options for displaying a field, such as the order in which a field is displayed and whether a field will be used as a filter. The attribute also provides independent control of the name used for the labels in a *GridView* control, the name used in a *DetailsView* control, the help text for the field, and the watermark used for the field (if the field accepts text input).

The *EnumDataTypeAttribute* class has been added to let you map fields to enumerations. When you apply this attribute to a field, you specify an enumeration type. Dynamic Data uses the new `Enumeration.ascx` field template to create UI for displaying and editing enumeration values. The template maps the values from the database to the names in the enumeration.

Enhanced Support for Filters

Dynamic Data 1.0 shipped with built-in filters for Boolean columns and foreign-key columns. The filters did not allow you to specify whether they were displayed or in what order they were displayed. The new *DisplayAttribute* attribute addresses both of these issues by giving you control over whether a column is displayed as a filter and in what order it will be displayed.

An additional enhancement is that filtering support has been rewritten to use the new feature of Web Forms. This lets you create filters without requiring knowledge of the data source control that the filters will be used with. Along with these extensions, filters have also been turned into template controls, which allows you to add new ones. Finally, the *DisplayAttribute* class mentioned earlier allows the default filter to be overridden, in the same way that *UIHint* allows the default field template for a column to be overridden.

Visual Studio 2010 Web Development Improvements

Web development in Visual Studio 2010 has been enhanced for greater CSS compatibility, increased productivity through HTML and ASP.NET markup snippets and new dynamic IntelliSense JavaScript.

Improved CSS Compatibility

The Visual Web Developer designer in Visual Studio 2010 has been updated to improve CSS 2.1 standards compliance. The designer better preserves integrity of the HTML source and is more robust than in previous versions of Visual Studio. Under the hood, architectural improvements have also been made that will better enable future enhancements in rendering, layout, and serviceability.

HTML and JavaScript Snippets

In the HTML editor, IntelliSense auto-completes tag names. The IntelliSense Snippets feature auto-completes entire tags and more. In Visual Studio 2010, IntelliSense snippets are supported for JavaScript, alongside C# and Visual Basic, which were supported in earlier versions of Visual Studio.

Visual Studio 2010 includes over 200 snippets that help you auto-complete common ASP.NET and HTML tags, including required attributes (such as runat="server") and common attributes specific to a tag (such as *ID*, *DataSourceID*, *ControlToValidate*, and *Text*).

You can download additional snippets, or you can write your own snippets that encapsulate the blocks of markup that you or your team use for common tasks.

JavaScript IntelliSense Enhancements

In Visual 2010, JavaScript IntelliSense has been redesigned to provide an even richer editing experience.

IntelliSense now recognizes objects that have been dynamically generated by methods such as *registerNamespace* and by similar techniques used by other JavaScript frameworks. Performance has been improved to analyze large libraries of script and to display IntelliSense with little or no processing delay. Compatibility has been dramatically increased to support nearly all third-party libraries and to support diverse coding styles. Documentation comments are now parsed as you type and are immediately leveraged by IntelliSense.

Web Application Deployment with Visual Studio 2010

When ASP.NET developers deploy a Web application, they often find that they encounter issues such as the following:

- Deploying to a shared hosting site requires technologies such as FTP, which can be slow. In addition, you must manually perform tasks such as running SQL scripts to configure a database and you must change IIS settings, such as configuring a virtual directory folder as an application.
- In an enterprise environment, in addition to deploying the Web application files, administrators frequently must modify ASP.NET configuration files and IIS settings. Database administrators must run a series of SQL scripts to get the application database running. Such installations are labor intensive, often take hours to complete, and must be carefully documented.

Visual Studio 2010 includes technologies that address these issues and that let you seamlessly deploy Web applications. One of these technologies is the IIS Web Deployment Tool (MsDeploy.exe).

Web deployment features in Visual Studio 2010 include the following major areas:

- Web packaging
- Web.config transformation
- Database deployment
- One-click publish for Web applications

The following sections provide details about these features.

Web Packaging

Visual Studio 2010 uses the MSDeploy tool to create a compressed (.zip) file for your application, which is referred to as a *Web package*. The package file contains metadata about your application plus the following content:

- IIS settings, which includes application pool settings, error page settings, and so on.
- The actual Web content, which includes Web pages, user controls, static content (images and HTML files), and so on.
- SQL Server database schemas and data.
- Security certificates, components to install in the GAC, registry settings, and so on.

A Web package can be copied to any server and then installed manually by using IIS Manager. Alternatively, for automated deployment, the package can be installed by using command-line commands or by using deployment APIs.

Visual Studio 2010 provides built in MSBuild tasks and targets to create Web packages. For more information, see ASP.NET Web Application Project Deployment Overview on the MSDN Web site and 10 + 20 reasons why you should create a Web Package on Vishal Joshi's blog.

Web.config Transformation

For Web application deployment, Visual Studio 2010 introduces XML Document Transform (XDT), which is a feature that lets you transform a `Web.config` file from development settings to production settings. Transformation settings are specified in transform files named `web.debug.config`, `web.release.config`, and so on. (The names of these files match MSBuild configurations.) A transform file includes just the changes that you need to make to a deployed `Web.config` file. You specify the changes by using simple syntax.

The following example shows a portion of a `web.release.config` file that might be produced for deployment of your release configuration. The Replace keyword in the example specifies that during deployment the *connectionString* node in the `Web.config` file will be replaced with the values that are listed in the example.

```
<connectionStrings xdt:Transform="Replace">
  <add name="BlogDB" connectionString="connection string detail]" />

</connectionStrings>
```

For more information, see Web.config Transformation Syntax for Web Application Project Deployment on the MSDN Web site andWeb Deployment: Web.Config Transformation on Vishal Joshi's blog.

Database Deployment

A Visual Studio 2010 deployment package can include dependencies on SQL Server databases. As part of the package definition, you provide the connection string for your source database. When you create the Web package, Visual Studio 2010 creates SQL scripts for the database schema and optionally for the data, and then adds these to the package. You can also provide custom SQL scripts and specify the sequence in which they should run on the server. At deployment time, you provide a connection string that is appropriate for the target server; the deployment process then uses this connection string to run the scripts that create the database schema and add the data.

In addition, by using one-click publish, you can configure deployment to publish your database directly when the application is published to a remote shared hosting site. For more information, see How to: Deploy a Database With a Web Application Project on the MSDN Web site and Database Deployment with VS 2010 on Vishal Joshi's blog.

One-Click Publish for Web Applications

Visual Studio 2010 also lets you use the IIS remote management service to publish a Web application to a remote server. You can create a publish profile for your hosting account or for testing servers or staging servers. Each profile can save appropriate credentials securely. You can then deploy to any of the target servers with one click by using the Web one-click publish toolbar. With Visual Studio 2010, you can also publish by using the MSBuild command line. This lets you configure your team build environment to include publishing in a continuous-integration model.

For more information, see How to: Deploy a Web Application Project Using One-Click Publish and Web Deploy on the MSDN Web site and Web 1-Click Publish with VS 2010 on Vishal Joshi's blog. To view video presentations about Web application deployment in Visual Studio 2010, see VS 2010 for Web Developer Previews on Vishal Joshi's blog.

ControlRenderingCompatibilityVersion Setting in the Web.config File
ClientIDMode Changes
HtmlEncode and UrlEncode Now Encode Single Quotation Marks
ASP.NET Page (.aspx) Parser is Stricter
Browser Definition Files Updated
System.Web.Mobile.dll Removed from Root Web Configuration File
ASP.NET Request Validation
Default Hashing Algorithm Is Now HMACSHA256
Configuration Errors Related to New ASP.NET 4 Root Configuration
ASP.NET 4 Child Applications Fail to Start When Under ASP.NET 2.0 or ASP.NET 3.5 Applications
ASP.NET 4 Web Sites Fail to Start on Computers Where SharePoint Is Installed
The HttpRequest.FilePath Property No Longer Includes PathInfo Values
ASP.NET 2.0 Applications Might Generate HttpException Errors that Reference eurl.axd
Event Handlers Might Not Be Not Raised in a Default Document in IIS 7 or IIS 7.5 Integrated Mode
Changes to the ASP.NET Code Access Security (CAS) Implementation
MembershipUser and Other Types in the System.Web.Security Namespace Have Been Moved
Output Caching Changes to Vary * HTTP Header
System.Web.Security Types for Passport are Obsolete
The MenuItem.PopOutImageUrl Property Fails to Render an Image in ASP.NET 4
Menu.StaticPopOutImageUrl and Menu.DynamicPopOutImageUrl Fail to Render Images When Paths Contain Backslashes
Disclaimer

ControlRenderingCompatibilityVersion Setting in the Web.config File

ASP.NET controls have been modified in the .NET Framework version 4 in order to let you specify more precisely how they render markup. In previous versions of the .NET Framework, some controls emitted markup that you had no way to disable. By default, ASP.NET 4 this type of markup is no longer generated.

If you use Visual Studio 2010 to upgrade your application from ASP.NET 2.0 or ASP.NET 3.5, the tool automatically adds a setting to the `Web.config` file that preserves legacy rendering. However, if you upgrade an application by changing the application pool in IIS to target the .NET Framework 4, ASP.NET uses the new rendering mode by default. To disable the new rendering mode, add the following setting in the `Web.config` file:

```
<pages controlRenderingCompatibilityVersion="3.5" />
```

The major rendering changes that the new behavior brings are as follows:

- The **Image** and **ImageButton** controls no longer render a `border="0"` attribute.
- The **BaseValidator** class and validation controls that derive from it no longer render red text by default.
- The **HtmlForm** control does not render a **name** attribute.
- The **Table** control no longer renders a `border="0"` attribute.
- Controls that are not designed for user input (for example, the **Label** control) no longer render the `disabled="disabled"` attribute if their **Enabled** property is set to **false** (or if they inherit this setting from a container control).

ClientIDMode Changes

The **ClientIDMode** setting in ASP.NET 4 lets you specify how ASP.NET generates the **id** attribute for HTML elements. In previous versions of ASP.NET, the default behavior was equivalent to the **AutoID** setting of **ClientIDMode**. However, the default setting is now **Predictable**.

If you use Visual Studio 2010 to upgrade your application from ASP.NET 2.0 or ASP.NET 3.5, the tool automatically adds a setting to the `Web.config` file that preserves the behavior of earlier versions of the .NET Framework. However, if you upgrade an application by changing the application pool in IIS to target the .NET Framework 4, ASP.NET uses the new mode by default. To disable the new client ID mode, add the following setting in the `Web.config` file:

```
<pages clientIDMode="AutoID" />
```

HtmlEncode and UrlEncode Now Encode Single Quotation Marks

In ASP.NET 4, the **HtmlEncode** and **UrlEncode** methods of the **HttpUtility** and **HttpServerUtility** classes have been updated to encode the single quotation mark character (') as follows:

- The **HtmlEncode** method encodes instances of the single quotation mark as ' .
- The **UrlEncode** method encodes instances of the single quotation mark as %27.

ASP.NET Page (.aspx) Parser is Stricter

The page parser for ASP.NET pages (`.aspx` files) and user controls (`.ascx` files) is stricter in ASP.NET 4 and will reject more instances of invalid markup. For example, the following two snippets would successfully parse in earlier releases of ASP.NET, but will now raise parser errors in ASP.NET 4.

```
<asp:HiddenField runat="server" ID="SomeControl" Value="sampleValue"  ; />
```

Notice the invalid semicolon at the end of the **HiddenField** tag.

```
<asp:LinkButton runat="server" ID="SomeControl" onclick="someControlClicked"
      style="display:inline;  CssClass="searchLink"  />
```

Notice the unclosed **style** attribute that runs into the **CssClass** attribute.

Browser Definition Files Updated

The browser definition files have been updated to include information about new and updated browsers and devices. Older browsers and devices such as Netscape Navigator have been removed, and newer browsers and devices such as Google Chrome and Apple iPhone have been added.

If your application contains custom browser definitions that inherit from one of the browser definitions that have

been removed, you will see an error. For example, if the `App_Browsers` folder contains a browser definition that inherits from the IE2 browser definition, you will receive the following configuration error message:

- The browser or gateway element with ID 'IE2' cannot be found.

> **NOTE**
>
> The **HttpBrowserCapabilities** object (which is exposed by the page's **Request.Browser** property) is driven by the browser definitions files. Therefore, the information returned by accessing a property of this object in ASP.NET 4 might be different than the information returned in an earlier version of ASP.NET.

You can revert to the old browser definition files by copying the browser definition files from the following folder:

```
Windows\Microsoft.NET\Framework\v2.0.50727\CONFIG\Browsers
```

Copy the files into the corresponding `\CONFIG\Browsers` folder for ASP.NET 4. After you copy the files, run the Aspnet_regbrowsers.exe command-line tool.

System.Web.Mobile.dll Removed from Root Web Configuration File

In previous versions of ASP.NET, a reference to the System.Web.Mobile.dll assembly was included in the root `Web.config` file in the **assemblies** section under. In order to improve performance, the reference to this assembly was removed.

The System.Web.Mobile.dll assembly is included in ASP.NET 4, but it is deprecated. If you want to use types from the System.Web.Mobile.dll assembly, add a reference to this assembly to either the root `Web.config` file or to an application `Web.config` file. For example, if you want to use any of the (deprecated) ASP.NET mobile controls, you must add a reference to the System.Web.Mobile.dll assembly to the `Web.config` file.

ASP.NET Request Validation

The request validation feature in ASP.NET provides a certain level of default protection against cross-site scripting (XSS) attacks. In previous versions of ASP.NET, request validation was enabled by default. However, it applied only to ASP.NET pages (`.aspx` files and their class files) and only when those pages were executing.

In ASP.NET 4, by default, request validation is enabled for all requests, because it is enabled before the **BeginRequest** phase of an HTTP request. As a result, request validation applies to requests for all ASP.NET resources, not just .aspx page requests. This includes requests such as Web service calls and custom HTTP handlers. Request validation is also active when custom HTTP modules are reading the contents of an HTTP request.

As a result, request validation errors might now occur for requests that previously did not trigger errors. To revert to the behavior of the ASP.NET 2.0 request validation feature, add the following setting in the `Web.config` file:

```
<httpRuntime requestValidationMode="2.0" />
```

However, we recommend that you analyze any request validation errors to determine whether existing handlers, modules, or other custom code accesses potentially unsafe HTTP inputs that could be XSS attack vectors.

Default Hashing Algorithm Is Now HMACSHA256

ASP.NET uses both encryption and hashing algorithms to help secure data such as forms authentication cookies and view state. By default, ASP.NET 4 now uses the HMACSHA256 algorithm for hash operations on cookies and

view state. Earlier versions of ASP.NET used the older HMACSHA1 algorithm.

Your applications might be affected if you run mixed ASP.NET 2.0/ASP.NET 4 environments where data such as forms authentication cookies must work across.NET Framework versions. To configure an ASP.NET 4 Web application to use the older HMACSHA1 algorithm, add the following setting in the `Web.config` file:

```
<machineKey validation="SHA1" />
```

Configuration Errors Related to New ASP.NET 4 Root Configuration

The root configuration files (the `machine.config` file and the root `Web.config` file) for the .NET Framework 4 (and therefore ASP.NET 4) have been updated to include most of the boilerplate configuration information that in ASP.NET 3.5 was found in the application `Web.config` files. Because of the complexity of the managed IIS 7 and IIS 7.5 configuration systems, running ASP.NET 3.5 applications under ASP.NET 4 and under IIS 7 and IIS 7.5 can result in either ASP.NET or IIS configuration errors.

We recommend that you upgrade ASP.NET 3.5 applications to ASP.NET 4 by using the project upgrade tools in Visual Studio 2010, if practical. Visual Studio 2010 automatically modifies the ASP.NET 3.5 application's `Web.config` file to contain the appropriate settings for ASP.NET 4.

However, it is a supported scenario to run ASP.NET 3.5 applications using the .NET Framework 4 without recompilation. In that case, you might have to manually modify the application's `Web.config` file before you run the application under the .NET Framework 4 and under IIS 7 or IIS 7.5.

The next two sections describe changes that you might need to make for different combinations of software.

Windows Vista SP1 or Windows Server 2008 SP1, where neither hotfix KB958854 nor SP2 are installed. In this configuration, the IIS 7 configuration system incorrectly merges an application's managed configuration by comparing the application-level `Web.config` file to the ASP.NET 2.0 `machine.config` files. Because of this, application-level `Web.config` files from the .NET Framework 3.5 or later must have a **system.web.extensions** configuration section definition (the element) in order not to cause an IIS 7 validation failure.

However, manually modified application-level `Web.config` file entries that do not precisely match the original boilerplate configuration section definitions that were introduced with Visual Studio 2008 will cause ASP.NET configuration errors. (The default configuration entries that are generated by Visual Studio 2008 work correctly.) A common problem is that manually modified `Web.config` files leave out the **allowDefinition** and **requirePermission** configuration attributes that are found on various configuration section definitions. This causes a mismatch between the abbreviated configuration section in application-level `Web.config` files and the complete definition in the ASP.NET 4 `machine.config` file. As a result, at run time, the ASP.NET 4 configuration system throws a configuration error.

Windows Vista SP2, Windows Server 2008 SP2, Windows 7, Windows Server 2008 R2, and also Windows Vista SP1 and Windows Server 2008 SP1 where hotfix KB958854 is installed.

In this scenario, the IIS 7 and IIS 7.5 native configuration system returns a configuration error because it performs a text comparison on the **type** attribute that is defined for a managed configuration section handler. Because all `Web.config` files that are generated by Visual Studio 2008 and Visual Studio 2008 SP1 have "3.5" in the type string for the **system.web.extensions** (and related) configuration section handlers, and because the ASP.NET 4 `machine.config` file has "4.0" in the **type** attribute for the same configuration section handlers, applications that are generated in Visual Studio 2008 or Visual Studio 2008 SP1 always fail configuration validation in IIS 7 and IIS 7.5.

Resolving These Issues

The workaround for the first scenario is to update the application-level `Web.config` file by including the boilerplate configuration text from a `Web.config` file that was generated automatically by Visual Studio 2008.

An alternative workaround for the first scenario is to install Service Pack 2 for Vista or Windows Server 2008 on your computer or to install hotfix KB958854 (https://support.microsoft.com/kb/958854) to fix the incorrect configuration-merge behavior of the IIS configuration system. However, after you perform either of these actions, your application will likely encounter a configuration error due to the issue described for the second scenario.

The workaround for the second scenario is to delete or comment out all the **system.web.extensions** configuration section definitions and configuration section group definitions from the application-level `Web.config` file. These definitions are usually at the top of the application-level `Web.config` file and can be identified by the **configSections** element and its children.

For both scenarios, it is recommended that you also manually delete the **system.codedom** section, although this is not required.

ASP.NET 4 Child Applications Fail to Start When Under ASP.NET 2.0 or ASP.NET 3.5 Applications

ASP.NET 4 applications that are configured as children of applications that run earlier versions of ASP.NET might fail to start because of configuration or compilation errors. The following example shows a directory structure for an affected application.

`/parentwebapp` (configured to use ASP.NET 2.0 or ASP.NET 3.5)
`/childwebapp` (configured to use ASP.NET 4)

The application in the `childwebapp` folder will fail to start on IIS 7 or IIS 7.5 and will report a configuration error. The error text will include a message similar to the following:

- `The requested page cannot be accessed because the related configuration data for the page is invalid.`
- `The configuration section 'configSections' cannot be read because it is missing a section declaration.`

On IIS 6, the application in the `childwebapp` folder will also fail to start, but it will report a different error. For example, the error text might state the following:

- ```
  The value for the 'compilerVersion' attribute in the provider options must be 'v4.0' or later if you are compiling for version 4.0 or later of the .NET Framework. To compile this Web application for version 3.5 or earlier of the .NET Framework, remove the 'targetFramework' attribute from the element of the Web.config file
  ```

These scenarios occur because the configuration information from the parent application in the `parentwebapp` folder is part of the hierarchy of configuration information that determines the final merged configuration settings that are used by the child web application in the `childwebapp` folder. Depending on whether the ASP.NET 4 Web application is running on IIS 7 (or IIS 7.5) or on IIS 6, either the IIS configuration system or the ASP.NET 4 compilation system will return an error.

The steps that you must follow to resolve this issue and to get the child ASP.NET 4 application to work depend on whether the ASP.NET 4 application runs on IIS 6 or on IIS 7 (or IIS 7.5).

Step 1 (IIS 7 or IIS 7.5 only)

This step is necessary only on operating systems that run IIS 7 or IIS 7.5, which includes Windows Vista, Windows Server 2008, Windows 7, and Windows Server 2008 R2.

Move the **configSections** definition in the `Web.config` file of the parent application (the application that runs ASP.NET 2.0 or ASP.NET 3.5) into the root `Web.config` file for the.NET Framework 2.0. The IIS 7 and IIS 7.5 native configuration system scans the **configSections** element when it merges the hierarchy of configuration files. Moving the **configSections** definition from the parent Web application's `Web.config` file to the root `Web.config`
  ```

file effectively hides the element from the configuration merge process that occurs for the child ASP.NET 4 application.

On a 32-bit operating system or for 32-bit application pools, the root `Web.config` file for ASP.NET 2.0 and ASP.NET 3.5 is normally located in the following folder:

`C:\Windows\Microsoft.NET\Framework\v2.0.50727\CONFIG`

On a 64-bit operating system or for 64-bit application pools, the root `Web.config` file for ASP.NET 2.0 and ASP.NET 3.5 is normally located in the following folder:

`C:\Windows\Microsoft.NET\Framework64\v2.0.50727\CONFIG`

If you run both 32-bit and 64-bit Web applications on a 64-bit computer, you must move the **configSections** element up into root `Web.config` files for both the 32-bit and the 64-bit systems.

When you put the **configSections** element in the root `Web.config` file, paste the section immediately after the **configuration** element. The following example shows what the top portion of the root `Web.config` file should look like when you have finished moving the elements.

> **NOTE**
>
> In the following example, lines have been wrapped for readability.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- The root web configuration file -->
<configuration>
  <configSections>
    <sectionGroup name="system.web.extensions"
        type="System.Web.Configuration.SystemWebExtensionsSectionGroup,
      System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
      PublicKeyToken=31BF3856AD364E35">

      <sectionGroup name="scripting"
        type="System.Web.Configuration.ScriptingSectionGroup,
        System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
        PublicKeyToken=31BF3856AD364E35">

        <section name="scriptResourceHandler"
          type="System.Web.Configuration.ScriptingScriptResourceHandlerSection,
          System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
          PublicKeyToken=31BF3856AD364E35" requirePermission="false"
          allowDefinition="MachineToApplication" />

        <sectionGroup name="webServices"
          type="System.Web.Configuration.ScriptingWebServicesSectionGroup,
          System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
          PublicKeyToken=31BF3856AD364E35">

          <section name="jsonSerialization"
            type="System.Web.Configuration.ScriptingJsonSerializationSection,
            System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
            PublicKeyToken=31BF3856AD364E35" requirePermission="false"
            allowDefinition="Everywhere" />

          <section name="profileService"
            type="System.Web.Configuration.ScriptingProfileServiceSection,
            System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
            PublicKeyToken=31BF3856AD364E35" requirePermission="false"
            allowDefinition="MachineToApplication" />
          <section name="authenticationService"
            type="System.Web.Configuration.ScriptingAuthenticationServiceSection,
          System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
          PublicKeyToken=31BF3856AD364E35" requirePermission="false"
            allowDefinition="MachineToApplication" />

          <section name="roleService"
            type="System.Web.Configuration.ScriptingRoleServiceSection,
          System.Web.Extensions, Version=3.5.0.0, Culture=neutral,
          PublicKeyToken=31BF3856AD364E35" requirePermission="false"
            allowDefinition="MachineToApplication" />

        </sectionGroup>
      </sectionGroup>
    </sectionGroup>
  </configSections>
```

Step 2 (all versions of IIS)

This step is required whether the ASP.NET 4 child Web application is running on IIS 6 or on IIS 7 (or IIS 7.5).

In the `Web.config` file of the parent Web application that is running ASP.NET 2 or ASP.NET 3.5, add a **location** tag that explicitly specifies (for both the IIS and ASP.NET configuration systems) that the configuration entries only apply to the parent Web application. The following example shows the syntax of the **location** element to add:

```
<location path="" inheritInChildApplications="false" >
  <!-- Additional settings -->
</location>
```

The following example shows how the **location** tag is used to wrap all configuration sections starting with the **appSettings** section and ending with **system.webServer** section.

```
<location path="" inheritInChildApplications="false" >
  <appSettings />
  <connectionStrings />
  <system.web>
    <!-- Removed for brevity -->
  </system.web>
  <system.codedom>
    <!-- Removed for brevity -->
  </system.codedom>
  <system.webServer>
    <!-- Removed for brevity -->
</system.webServer>
</location>
```

When you have completed steps 1 and 2, child ASP.NET 4 Web applications will start without errors.

ASP.NET 4 Web Sites Fail to Start on Computers Where SharePoint Is Installed

Web servers that run SharePoint have a `Web.config` file that is deployed at the root of a SharePoint Web site (for example, `c:\inetpub\wwwroot\web.config` for Default Web Site). In this `Web.config` file, SharePoint sets a custom partial-trust level named WSS_Minimal.

If you try to run an ASP.NET 4 Web site that is deployed as a child of this type of SharePoint Web site, you will see the following error:

`Could not find permission set named 'ASP.NET'.`

This error occurs because the ASP.NET 4 code access security (CAS) infrastructure looks for a permission set named ASP.NET. However, the partial trust configuration file that is referenced by WSS_Minimal does not contain any permission sets with that name.

Currently there is not a version of SharePoint available that is compatible with ASP.NET. As a result, you should not attempt to run an ASP.NET 4 Web site as a child site underneath SharePoint Web sites.

The HttpRequest.FilePath Property No Longer Includes PathInfo Values

Previous versions of ASP.NET included a **PathInfo** value in the value returned from various file path-related properties, including **HttpRequest.FilePath**, **HttpRequest.AppRelativeCurrentExecutionFilePath**, and **HttpRequest.CurrentExecutionFilePath**. ASP.NET 4 no longer includes the **PathInfo** value in the return values from these properties. Instead, the **PathInfo** information is available in **HttpRequest.PathInfo**. For example, imagine the following URL fragment:

`/testapp/Action.mvc/SomeAction`

In earlier versions of ASP.NET, **HttpRequest** properties have the following values:

HttpRequest.FilePath: `/testapp/Action.mvc/SomeAction`

HttpRequest.PathInfo: (empty)

In ASP.NET 4, **HttpRequest** properties instead have the following values:

HttpRequest.FilePath: `/testapp/Action.mvc`

HttpRequest.PathInfo: `SomeAction`

ASP.NET 2.0 Applications Might Generate HttpException Errors that Reference eurl.axd

After ASP.NET 4 has been enabled on IIS 6, ASP.NET 2.0 applications that run on IIS 6 (in either Windows Server 2003 or Windows Server 2003 R2) might generate errors such as the following:

```
System.Web.HttpException: Path '/[yourApplicationRoot]/eurl.axd/[Value]' was not found.
```

This error occurs because when ASP.NET detects that a Web site is configured to use ASP.NET 4, a native component of ASP.NET 4 passes an extensionless URL to the managed portion of ASP.NET for further processing. However, if virtual directories that are below an ASP.NET 4 Web site are configured to use ASP.NET 2.0, processing the extensionless URL in this way results in a modified URL that contains the string "eurl.axd". This modified URL is then sent to the ASP.NET 2.0 application. ASP.NET 2.0 cannot recognize the "eurl.axd" format. Therefore, ASP.NET 2.0 tries to find a file named `eurl.axd` and execute it. Because no such file exists, the request fails with an **HttpException** exception.

You can work around this issue using one of the following options.

Option 1

If ASP.NET 4 is not required in order to run the Web site, remap the site to use ASP.NET 2.0 instead.

Option 2

If ASP.NET 4 is required in order to run the Web site, move any child ASP.NET 2.0 virtual directories to a different Web site that is mapped to ASP.NET 2.0.

Option 3

If it is not practical to remap the Web site to ASP.NET 2.0 or to change the location of a virtual directory, explicitly disable extensionless URL processing in ASP.NET 4. Use the following procedure:

1. In the Windows registry, open the following node:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\ASP.NET\4.0.30319.0
```

1. Create a new **DWORD** value named **EnableExtensionlessUrls**.
2. Set **EnableExtensionlessUrls** to 0. This disables extensionless URL behavior.
3. Save the registry value and close the registry editor.
4. Run the **iisreset** command-line tool, which causes IIS to read the new registry value.

> **NOTE**
>
> Setting **EnableExtensionlessUrls** to 1 enables extensionless URL behavior. This is the default setting if no value is specified.

Event Handlers Might Not Be Not Raised in a Default Document in IIS 7 or IIS 7.5 Integrated Mode

ASP.NET 4 includes modifications that change how the **action** attribute of the HTML **form** element is rendered when an extensionless URL resolves to a default document. An example of an extensionless URL resolving to a default document would be http://contoso.com/, resulting in a request to http://contoso.com/Default.aspx.

ASP.NET 4 now renders the HTML **form** element's **action** attribute value as an empty string when a request is made to an extensionless URL that has a default document mapped to it. For example, in earlier releases of ASP.NET, a request to http://contoso.com would result in a request to `Default.aspx`. In that document, the opening **form** tag would be rendered as in the following example:

```
<form action="Default.aspx" />
```

In ASP.NET 4, a request to http://contoso.com also results in a request to `Default.aspx`. However, ASP.NET now renders the HTML opening **form** tag as in the following example:

```
<form action="" />
```

This difference in how the **action** attribute is rendered can cause subtle changes in how a form post is processed by IIS and ASP.NET. When the **action** attribute is an empty string, the IIS **DefaultDocumentModule** object will create a child request to `Default.aspx`. Under most conditions, this child request is transparent to application code, and the `Default.aspx` page runs normally.

However, a potential interaction between managed code and IIS 7 or IIS 7.5 Integrated mode can cause managed .aspx pages to stop working properly during the child request. If the following conditions occur, the child request to a `Default.aspx` document will result in an error or in unexpected behavior:

1. An .aspx page is sent to the browser with the **form** element's **action** attribute set to "".
2. The form is posted back to ASP.NET.
3. A managed HTTP module reads some part of the entity body. For example, a module reads **Request.Form** or **Request.Params**. This causes the entity body of the POST request to be read into managed memory. As a result, the entity body is no longer available to any native code modules that are running in IIS 7 or IIS 7.5 Integrated mode.
4. The IIS **DefaultDocumentModule** object eventually runs and creates a child request to the `Default.aspx` document. However, because the entity body has already been read by a piece of managed code, there is no entity body available to send to the child request.
5. When the HTTP pipeline runs for the child request, the handler for `.aspx` files runs during the handler-execute phase.
6. Because there is no entity body, there are no form variables and no view state, and therefore no information is available for the .aspx page handler to determine what event (if any) is supposed to be raised. As a result, none of the postback event handlers for the affected .aspx page run.

You can work around this behavior in the following ways:

- Identify the HTTP module that is accessing the request's entity body during default document requests and determine whether it can be configured to run only for managed requests. In Integrated mode for both IIS 7 and IIS 7.5, HTTP modules can be marked to run only for managed requests by adding the following attribute to the module's **system.webServer/modules** entry:

- `precondition="managedHandler"`

- This setting disables the module for requests that IIS 7 and IIS 7.5 determine as not being managed requests. For default document requests, the first request is to an extensionless URL. Therefore, IIS does not run any managed modules that are marked with a precondition of managed Handler during initial request processing. As a result, managed modules will not accidentally read the entity body and thus the entity body is still available and is passed along to the child request and to the default document.

- If the problematic HTTP modules have to run for all requests (for static files, for extensionless URLs that resolve to the **DefaultDocumentModule** object, for managed requests, etc.), modify the affected .aspx pages by explicitly setting the **Action** property of the page's **System.Web.UI.HtmlControls.HtmlForm** control to a non-empty string. For example, if the default document is `Default.aspx`, modify the page's code to explicitly set the **HtmlForm** control's **Action** property to "Default.aspx".

Changes to the ASP.NET Code Access Security (CAS) Implementation

ASP.NET 2.0, and by extension the ASP.NET features that were added in 3.5, use the .NET Framework 1.1 and 2.0 code access security (CAS) model. However, the implementation of CAS in ASP.NET 4 has been substantially overhauled. As a result, partial-trust ASP.NET applications that rely on trusted code running in the global assembly

cache (GAC) might fail with various security exceptions. Partial-trust applications that rely on extensive modifications to machine CAS policy might also fail with security exceptions.

You can revert partial-trust ASP.NET 4 applications to the behavior of ASP.NET 1.1 and 2.0 using the new **legacyCasModel** attribute in the **trust** configuration element, as shown in the following example:

```
<trust level= "Medium" legacyCasModel="true" />
```

When you revert to the legacy CAS model, the following old CAS behaviors are enabled:

- Machine CAS policy is honored.
- Multiple different permission sets in a single application domain are allowed.
- Explicit permission assertions are not required for assemblies in the GAC that are invoked when only ASP.NET or other .NET Framework code is on the stack.

One scenario cannot be reverted in the .NET Framework 4: non-Web partial-trust applications can no longer call certain APIs in System.Web.dll and System.Web.Extensions.dll. In previous versions of the .NET Framework, it was possible for non-Web partial-trust applications to be explicitly granted **AspNetHostingPermission** permissions. These applications could then use **System.Web.HttpUtility**, types in the **System.Web.ClientServices.*** namespaces, and types related to membership, roles, and profiles. Calling these types from non-Web partial trust applications is no longer supported in the .NET Framework 4.

> **NOTE**
>
> The **HtmlEncode** and **HtmlDecode** functionality of the **System.Web.HttpUtility** class was moved to the new .NET Framework 4 **System.Net.WebUtility** class. If that was the only ASP.NET functionality that was being used, modify the application's code to use the new **WebUtility** class instead.

The following is a high-level summary of the changes to the default CAS implementation in ASP.NET 4:

- ASP.NET application domains are now homogeneous application domains. Only partial-trust and full-trust grant sets are available in an application domain.
- ASP.NET partial-trust grant sets are independent from any enterprise-level, machine-level, or user-level CAS policy.
- ASP.NET assemblies that shipped in 3.5 and 3.5 SP1 have been converted to use the .NET Framework 4 transparency model.
- Use of the ASP.NET **AspNetHostingPermission** attribute has been substantially reduced. Most instances of this attribute have been removed from the public ASP.NET APIs.
- Dynamically compiled assemblies that are created by ASP.NET build providers have been updated to explicitly mark assemblies as transparent.
- All ASP.NET assemblies are now marked in such a way that the APTCA attribute is honored only in Web hosting environments. Partially trusted non-Web hosting environments like ClickOnce will not be able to call into ASP.NET assemblies.

For more information about the new ASP.NET 4 code access security model, see Using Code Access Security in ASP.NET Applications on the MSDN Web site.

MembershipUser and Other Types in the System.Web.Security Namespace Have Been Moved

Some types that are used in ASP.NET membership have been moved from `System.Web.dll` to the new System.Web.ApplicationServices.dll assembly. The types were moved in order to resolve architectural layering dependencies between types in the client and in extended .NET Framework SKUs.

Web site projects do not have problems as a result of moving these types, because System.Web.ApplicationServices.dll was added to the list of referenced assemblies that is used by default by the ASP.NET compilation system. If you upgrade a Web site project that was created using an earlier version of ASP.NET to ASP.NET 4 by opening it in Visual Studio 2010, the project will compile without errors.

Similarly, if you upgrade a Web application project that was created in an earlier version of ASP.NET to ASP.NET 4 by opening it in Visual Studio 2010, the upgrade process adds a reference to System.Web.ApplicationServices.dll to the project. Therefore, upgraded Web application projects will also compile without errors.

Compiled (binary) files that were created using earlier versions of ASP.NET will also run without errors on ASP.NET 4, even though the membership types were moved to a different assembly. Type forwarding information has been added to the ASP.NET 4 version of `System.Web.dll` that automatically routes run-time references for these types to the new location for the types.

However, class libraries that use specific membership types and that have been upgraded from earlier versions of ASP.NET will fail to compile when used in an ASP.NET 4 project. For example, a class library project might fail to compile and report an error such as the following:

- ```
  The type 'System.Web.Security.MembershipUser' is defined in an assembly that is not referenced. You must add a reference to assembly 'System.Web.ApplicationServices, Version=4.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35'.
  ```
- ```
  The type name 'MembershipUser' could not be found. This type has been forwarded to assembly 'System.Web.ApplicationServices, Version=4.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35'. Consider adding a reference to that assembly.
  ```

You can work around this problem by adding a reference in your class library project to System.Web.ApplicationServices.dll.

The following list shows the *System.Web.Security* types that were moved from `System.Web.dll` to System.Web.ApplicationServices.dll:

- *System.Web.Security.MembershipCreateStatus*
- *System.Web.Security.Membership.CreateUserException*
- *System.Web.Security.MembershipPasswordException*
- *System.Web.Security.MembershipPasswordFormat*
- *System.Web.Security.MembershipProvider*
- *System.Web.Security.MembershipProviderCollection*
- *System.Web.Security.MembershipUser*
- *System.Web.Security.MembershipUserCollection*
- *System.Web.Security.MembershipValidatePasswordEventHandler*
- *System.Web.Security.ValidatePasswordEventArgs*
- *System.Web.Security.RoleProvider*
- *System.Web.Configuration.MembershipPasswordCompatibilityMode*

Output Caching Changes to Vary * HTTP Header

In ASP.NET 1.0, a bug caused cached pages that specified `Location="ServerAndClient"` as an output–cache setting to emit a `Vary:*` HTTP header in the response. This had the effect of telling client browsers to never cache the page locally.

In ASP.NET 1.1, the **System.Web.HttpCachePolicy.SetOmitVaryStar** method was added, which you could call to suppress the `Vary:*` header. This method was chosen because changing the emitted HTTP header was considered a potentially breaking change at the time. However, developers have been confused by the behavior in ASP.NET, and bug reports suggest that developers are unaware of the existing **SetOmitVaryStar** behavior.

In ASP.NET 4, the decision was made to fix the root problem. The `Vary:*` HTTP header is no longer emitted from responses that specify the following directive:

```
<%@OutputCache Location="ServerAndClient" %>
```

As a result, **SetOmitVaryStar** is no longer needed in order to suppress the `Vary:*` header.

In applications that specify `Location="ServerAndClient"` in the **@ OutputCache** directive on a page, you will now see the behavior implied by the name of the **Location** attribute's value – that is, pages will be cacheable in the browser without requiring that you call the **SetOmitVaryStar** method.

If pages in your application must emit `Vary:*`, call the **AppendHeader** method, as in the following example:

```
HttpResponse.AppendHeader("Vary","*");
```

Alternatively, you can change the value of the output caching **Location** attribute to "Server".

System.Web.Security Types for Passport are Obsolete

The Passport support built into ASP.NET 2.0 has been obsolete and unsupported for a few years due to changes in Passport (now LiveID). As a result, the five types related to Passport in **System.Web.Security** are now marked with the **ObsoleteAttribute** attribute.

The MenuItem.PopOutImageUrl Property Fails to Render an Image in ASP.NET 4

In ASP.NET 3.5, the *MenuItem.PopOutImageUrl* property lets you specify the URL for an image that is displayed in a menu item to indicate that the menu item has a dynamic submenu. The following example shows how to specify this property in markup in ASP.NET 3.5.

```
<asp:menu id="NavigationMenu"
    staticdisplaylevels="1"
    staticsubmenuindent="10"
    orientation="Vertical"
    target="_blank"
    runat="server">
  <items>
    <asp:menuitem navigateurl="default2.aspx"
        text="Home"
        PopOutImageUrl="~/Images/Popout.gif"
        tooltip="Home">
      <asp:menuitem navigateurl="default3.aspx"
          text="Movies"
          PopOutImageUrl="~/Images/Popout.gif"
          tooltip="Movies">
      </asp:menuitem>
    </asp:menuitem>
  </items>
</asp:menu>
```

As a result of a design change in ASP.NET 4, no output is rendered for the *PopOutImageUrl* if the property is set for the *MenuItem* class. Instead, you must specify an image URL directly in the *Menu* control using either the *StaticPopOutImageUrl* property or the *DynamicPopOutImageUrl* property. When you work with a static menu, the *Menu.StaticPopOutImageUrl* property specifies the URL for an image that is displayed in order to indicate that the static menu item has a submenu, as shown in the following example:

```
<asp:menu id="NavigationMenu"
    staticdisplaylevels="1"
    staticsubmenuindent="10"
    orientation="Vertical"
    target="_blank"
    StaticPopOutImageTextFormatString="More..."
    StaticPopOutImageUrl="Images/Popout.gif"
    runat="server">
  <items>
    <asp:menuitem navigateurl="default2.aspx"
        text="Home"
        tooltip="Home">
      <asp:menuitem navigateurl="default3.aspx"
          text="Movies"
          tooltip="Movies">
      </asp:menuitem>
    </asp:menuitem>
  </items>
</asp:menu>
```

If you are working with a dynamic menu, you use the *Menu.DynamicPopOutImageUrl* property to specify the URL for an image that indicates that a dynamic menu item has a submenu. The following example is similar to the previous one, but shows how to set the *DynamicPopOutImageUrl* property for a dynamic menu.

```
<asp:menu id="NavigationMenu"
    staticdisplaylevels="1"
    staticsubmenuindent="10"
    orientation="Vertical"
    target="_blank"
    DynamicPopOutImageTextFormatString="More..."
    DynamicPopOutImageUrl="Images/Popout.gif"
    runat="server">
  <items>
    <asp:menuitem navigateurl="default2.aspx"
        text="Home"
        tooltip="Home">
      <asp:menuitem navigateurl="default3.aspx"
          text="Movies"
          tooltip="Movies">
      </asp:menuitem>
    </asp:menuitem>
  </items>
</asp:menu>
```

If the *Menu.DynamicPopOutImageUrl* property is not set and the *Menu.DynamicEnableDefaultPopOutImage* property is set to *false*, no image is displayed. Similarly, if the *StaticPopOutImageUrl* property is not set and the *StaticEnableDefaultPopOutImage* property is set to *false*, no image is displayed.

When you set the paths for these properties, use a forward slash (/) instead of a backslash (). For more information, see Menu.StaticPopOutImageUrl and Menu.DynamicPopOutImageUrl Fail to Render Images When Paths Contain Backslashes elsewhere in this document.

Menu.StaticPopOutImageUrl and Menu.DynamicPopOutImageUrl Fail to Render Images When Paths Contain Backslashes

In ASP.NET 4, the images that you specify using the *Menu.StaticPopOutImageUrl* and *Menu.DynamicPopOutImageUrl* properties will not render if the path contains backlashes (). This is a change from earlier versions of ASP.NET.

The following example of *Menu* control markup shows the *StaticPopOutImageUrl* property set using a path that

contains a backslash. In ASP.NET 4, the image specified in the property will not render.

```
<asp:menu id="NavigationMenu"
    staticdisplaylevels="1"
    staticsubmenuindent="10"
    orientation="Vertical
    target="_blank"
    StaticPopOutImageTextFormatString="More..."
    StaticPopOutImageUrl="Images\Popout.gif"
    runat="server">
  <items>
    <asp:menuitem navigateurl="default2.aspx"
        text="Home"
        tooltip="Home">
      <asp:menuitem navigateurl="default3.aspx"
          text="Movies"
          tooltip="Movies">
      </asp:menuitem>
    </asp:menuitem>
  </items>
</asp:menu>
```

To correct this issue, change path values that are specified in the *StaticPopOutImageUrl* and *DynamicPopOutImageUrl* properties to use forward slashes (/). The following example shows this change:

```
<asp:menu id="NavigationMenu"
    staticdisplaylevels="1"
    staticsubmenuindent="10"
    orientation="Vertical
    target="_blank"
    StaticPopOutImageTextFormatString="More..."
    StaticPopOutImageUrl="Images/Popout.gif"
    runat="server">
  <items>
    <asp:menuitem navigateurl="default2.aspx"
        text="Home"
        tooltip="Home">
      <asp:menuitem navigateurl="default3.aspx"
          text="Movies"
          tooltip="Movies">
      </asp:menuitem>
    </asp:menuitem>
  </items>
</asp:menu>
```

Note that applications that were migrated from earlier versions of ASP.NET to ASP.NET 4 might also be affected, because the *MenuItem.PopOutImageUrl* property has been changed. For more information, see The MenuItem.PopOutImageUrl Property Fails to Render an Image in ASP.NET 4 elsewhere in this document.

Upgrading an ASP.NET MVC 1.0 Application to ASP.NET MVC 2

2/20/2020 • 2 minutes to read • Edit Online

This document describes both how to upgrade manually and with a wizard an ASP.NET MVC 1.0 Application to ASP.NET MVC 2. This document is also available for Download

Introduction

ASP.NET MVC 2 can be installed side by side with ASP.NET MVC 1.0 on the same server. This gives application developers flexibility in choosing when to upgrade an ASP.NET MVC 1.0 application to ASP.NET MVC 2.

Visual Studio 2010 includes a wizard that upgrades existing ASP.NET MVC 1.0 projects built with Visual Studio 2008 to ASP.NET MVC 2. The upgrade wizard is initiated by opening an ASP.NET MVC 1.0 project in Visual Studio 2010.

Upgrade Wizard for ASP.NET MVC 1.0 on Visual Studio 2008 SP1

To upgrade an ASP.NET MVC 1.0 application to ASP.NET MVC 2 in Visual Studio 2008 SP1, use the (unsupported) MvcAppConverter application. You can download this application from the following URL:

https://go.microsoft.com/fwlink/?LinkID=185351

Manually Upgrading an ASP.NET MVC 1.0 Project

To manually upgrade an existing ASP.NET MVC 1.0 application to version 2, follow these steps:

1. Make a backup of the existing project.
2. In a text editor, open the project file (the file with the .csproj or .vbproj file extension) and find the ProjectTypeGuid element. As the value of that element, replace the GUID {603c0e0b-db56-11dc-be95-000d561079b0} with {F85E285D-A4E0-4152-9332-AB1D724D3325}. When you are done, the value of that element should be as follows:

   ```
   {F85E285D-A4E0-4152-9332-AB1D724D3325};{349c5851-65df-11da-9384-00065b846f21};{fae04ec0-301f-11d3-bf4b-00c04f79efbc}
   ```

3. In the Web application root folder, edit the Web.config file. Search for System.Web.Mvc, Version=1.0.0.0 and replace all instances with System.Web.Mvc, Version=2.0.0.0.
4. Repeat the previous step for the Web.config file located in the Views folder.
5. Open the project using Visual Studio, and in **Solution Explorer**, expand the **References** node. Delete the reference to System.Web.Mvc (which points to the version 1.0 assembly). Add a reference to System.Web.Mvc (v2.0.0.0).
6. Add the following bindingRedirect element to the Web.config file in the application root under the configuraton section:

```
<runtime>
     <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
       <dependentAssembly>
         <assemblyIdentity name="System.Web.Mvc"

   publicKeyToken="31bf3856ad364e35"/>
         <bindingRedirect oldVersion="1.0.0.0"
   newVersion="2.0.0.0"/>
       </dependentAssembly>
     </assemblyBinding>
   </runtime>
```

7. Create a new empty ASP.NET MVC 2 application. Copy the files from the Scripts folder of the new application into the Scripts folder of the existing application.
8. Update the existing applicationâ€™s CSS file with the CSS style definitions in the Site.css file.
9. Compile the application and run it. If any errors occur, refer to the Breaking Changes section of the What's New in ASP.NET MVC 2 page.

ASP.NET Denied Access to IIS Directories

2/20/2020 • 2 minutes to read • Edit Online

This whitepaper describes what you must do if a request to your ASP.NET application returns the error, "Denied Access to *DirectoryName* directory. Failed to start monitoring directory changes."

Applies to ASP.NET 1.0 and ASP.NET 1.1.

ASP.NET V1 RTM now runs using a less privileged windows account - registered as the "ASPNET" account on a local machine.

On some locked down systems, this account may not by default have read security access to a website's content directories, the application root directory, or the web site root directory. In this case you will receive the following error when requesting pages from a given web application:

To fix this you will need to change the security permissions on the appropriate directories.

Specifically, ASP.NET requires read, execute, and list access for the ASPNET account for the web site root (for example: c:\inetpub\wwwroot or any alternative site directory you may have configured in IIS), the content directory and the application root directory in order to monitor for configuration file changes. The application root corresponds to the folder path associated with the application virtual directory in the IIS Administration tool (inetmgr).

For example, consider the following application hierarchy under the wwwroot folder.

```
C:\inetpub\wwwroot\myapp\default.aspx
```

For this example, the ASPNET account needs the read permissions defined above for content in both the myapp and the wwwroot directory. A single inherited ACL on the root folder can also be optionally used for both directories if they're nested.

To add permissions to a directory, perform the following steps:

- Using the Windows explorer, navigate to the directory

- Right click on the directory folder and choose "Properties"
- Navigate to the "Security" tab on the property dialog
- Click the "Add" button and enter the machine name followed by the ASPNET account name. For example, on a machine named "webdev", you would enter webdev\ASPNET and hit "OK".
- Ensure that the ASPNET account has the "Read & Execute", "List Folder Contents", and "Read" checkboxes checked.
- Hit OK to dismiss the dialog and save the changes.

If desired, these changes can be automated using scripts or the "cacls.exe" tool that ships with Windows. For more information on the ASPNET account, please see the FAQ document.

If a given web application relies on having write or modify permissions to a particular folder or file, this can be granted by following the same procedure and checking the "Write" and/or "Modify" checkboxes.

On machines that allow Everyone or the Users group read access to these directories (which is the default configuration), no issues will be encountered and the above steps will not be required.

What's New in ASP.NET MVC 2

9/16/2020 • 17 minutes to read • Edit Online

This document describes new features and improvements introduced in ASP.NET MVC 2. This document is also available for Download

Introduction
Upgrading an ASP.NET MVC 1.0 Project to ASP.NET MVC 2
New Features
Templated Helpers
Areas
Support for Asynchronous Controllers
Support for DefaultValueAttribute in Action-Method Parameters
Support for Binding Binary Data with Model Binders
ModelMetadata and ModelMetadataProvider Classes
Support for DataAnnotations Attributes
Model-Validator Providers
Client-Side Validation
New Code Snippets for Visual Studio 2010
New RequireHttpsAttribute Action Filter
Overriding the HTTP Method Verb
New HiddenInputAttribute Class for Templated Helpers
Html.ValidationSummary Helper Method Can Display Model-Level Errors
T4 Templates in Visual Studio Generate Code that is Specific to the Target Version of the .NET FrameworkAPI Improvements
Breaking Changes
Disclaimer

Introduction

ASP.NET MVC 2 builds on ASP.NET MVC 1.0 and introduces a large set of enhancements and features that are focused on increasing productivity. This release is compatible with ASP.NET MVC 1.0, so all your knowledge, skills, code, and extensions for ASP.NET MVC 1.0 continue to apply.

For more information about ASP.NET MVC, visit the following resources:

- ASP.NET MVC documentation on MSDN
- The ASP.NET MVC Web site
- The ASP.NET MVC forums

Upgrading an ASP.NET MVC 1.0 Project to ASP.NET MVC 2

ASP.NET MVC 2 can be installed side by side with ASP.NET MVC 1.0 on the same server, which gives application developers flexibility in choosing when to upgrade an ASP.NET MVC 1.0 application to ASP.NET MVC 2. For information on how to upgrade, see the document Upgrading an ASP.NET MVC 1.0 Application to ASP.NET MVC 2.

New Features

This section describes features that have been introduced in the MVC 2 release.

Templated Helpers

Templated helpers let you automatically associate HTML elements for edit and display with data types. For example, when data of type System.DateTime is displayed in a view, a date-picker UI element can be automatically rendered. This is similar to how field templates work in ASP.NET Dynamic Data. For more information, see Using Templated Helpers to Display Data on the MSDN Web site.

Areas

Areas let you organize a large project into multiple smaller sections in order to manage the complexity of a large Web application. Each section ("area") typically represents a separate section of a large Web site and is used to group related sets of controllers and views. For more information, see Walkthrough: Organizing an ASP.NET MVC Application by Areas on the MSDN Web site.

To create a new area, in Solution Explorer, right-click the project, click Add, and then click Area. This displays a dialog box that prompts you for the area name. After you enter the area name, Visual Studio adds a new area to the project.

The following figure shows an example layout for a project with two areas, Admin and Blogs.

When you create an area, Visual Studio adds a class that derives from AreaRegistration to each area. This class is required in order to register the area and its routes, as shown in the following example:

```
namespace MyApplication.Areas.Blog {
    public class BlogAreaRegistration : AreaRegistration {
        public override string AreaName {
            get { return "blog"; }
        }

        public override void RegisterArea(AreaRegistrationContext context) {
            context.MapRoute(
                "blog_default",
                "blog/{controller}/{action}/{id}",
                new { action = "Index", id = UrlParameter.Optional }
            );

            context.MapRoute(
                "blog_whatsnew",
                "whats-new",
                new { action = "WhatsNew", id = UrlParameter.Optional  }
            );
        }
    }
}
```

The default project template for ASP.NET MVC 2 includes a call to the RegisterAllAreas method in the code for the Global.asax file. This method registers each area in the project by looking for all types that derive from the AreaRegistration class, instantiating an instance of the type, and then calling the RegisterArea method on the instance. The following example shows how this is done.

```
public class MyMvcApplication : HttpApplication {

    void App_Start() {
        AreaRegistration.RegisterAllAreas();
        RegisterRoutes(RouteTable.Routes);
    }

    public static void RegisterRoutes(RouteCollection routes) {
        routes.MapRoute("default", "{controller}/{action}/{id}", ...);
    }
}
```

If you do not specify the namespace in the RegisterArea method by calling the context.Namespaces.Add method, the namespace of the registration class is used by default.

Support for Asynchronous Controllers

ASP.NET MVC 2 now allows controllers to process requests asynchronously. This can lead to performance gains by allowing servers which frequently call blocking operations (like network requests) to call non-blocking counterparts instead. For more information, see the Using an Asynchronous Controller in ASP.NET MVC topic on MSDN.

Support for DefaultValueAttribute in Action-Method Parameters

The System.ComponentModel.DefaultValueAttribute class allows a default value to be supplied for the argument parameter to an action method. For example, assume that the following default route is defined:

```
{controller}/{action}/{id}
```

Also assume that the following controller and action method is defined:

```
public class ArticleController {
    public ActionResult View(int id, [DefaultValue(1)]int page) {
    }
}
```

Any of the following request URLs will invoke the View action method that is defined in the preceding example.

- /Article/View/123
- /Article/View/123?page=1 (Effectively the same as the previous request)
- /Article/View/123?page=2

Without the DefaultValueAttribute attribute, the first URL from the preceding list would not work, because the page argument is a non-nullable value type whose value has not been provided.

If your code is written in Visual Basic 2010 or Visual C# 2010, you can use optional parameters instead of the DefaultValueAttribute attribute, as shown in the following example:

```
Function View(ByVal id As Integer, Optional ByVal page As Integer = 1) _
        As ActionResult
    ' ...
End Function

public ActionResult MyAction(int id, int page = 1) {
    // ...
}
```

Support for Binding Binary Data with Model Binders

There are two new overloads of the Html.Hidden helper that encode binary values as base-64-encoded strings:

```
public static string Hidden(this HtmlHelper htmlHelper, string name, Binary value);

public static string Hidden(this HtmlHelper htmlHelper, string name, byte[] value);
```

A typical use is to embed a timestamp for an object in the view. For example, your application might include the following Product object:

```
public class Product {
    //... other properties ...
    public byte[] TimeStamp {
        get;
        set;
    }
}
```

An edit form can render the TimeStamp property in the form as shown in the following example:

```
<%@ Page Inherits="ViewPage<Product>" %>
<%= Html.Hidden("TimeStamp", Model.TimeStamp) %>
```

This markup renders a hidden input element with the timestamp value as a base-64-encoded string that resembles the following example:

```
<input type="hidden" name="TimeStamp" value="QVNQLk5FVCBNVkMgaXMgZnVuIQ==" />
```

This form might be posted to an action method that has an argument of type Product, as shown in the following example:

```
public ActionResult Edit(Product p) {
    // p.TimeStamp is populated from the form
}
```

In the action method, the TimeStamp property is populated correctly because the posted base-64-encoded string is converted to a byte array.

ModelMetadata and ModelMetadataProvider Classes

The ModelMetadataProvider class provides an abstraction for obtaining metadata for the model within a view. MVC 2 includes a default provider that makes available the metadata that is exposed by the attributes in the System.ComponentModel.DataAnnotations namespace. It is possible to create metadata providers that provide metadata from other data stores, such as databases or XML files.

The ViewDataDictionary class exposes a ModelMetadata object that contains the metadata that is extracted from the model by the ModelMetadataProvider class. This enables the templated helpers to consume this metadata and adjust their output accordingly.

For more information, see the documentation for the ModelMetadata and ModelMetadataProvider classes.

Support for DataAnnotations Attributes

ASP.NET MVC 2 supports using the RangeAttribute, RequiredAttribute, StringLengthAttribute, and RegexAttribute validation attributes (defined in the System.ComponentModel.DataAnnotations namespace) when you bind to a model in order to provide input validation.

For more information, see How to: Validate Model Data Using DataAnnotations Attributes on the MSDN Web site. A sample project that illustrates the use of these attributes is available for download at https://go.microsoft.com/fwlink/?LinkId=157753.

Model-Validator Providers

The model-validation provider class represents an abstraction that provides validation logic for the model. ASP.NET MVC includes a default provider based on validation attributes that are included in the System.ComponentModel.DataAnnotations namespace. You can also create your own validation providers that define custom validation rules and custom mappings of validation rules to the model. For more information, see the documentation for the ModelValidatorProvider class.

Client-Side Validation

The model-validator provider class exposes validation metadata to the browser in the form of JSON-serialized data that can be consumed by a client-side validation library. ASP.NET MVC 2 includes a client validation library and adapter that supports the DataAnnotations namespace validation attributes noted earlier. The provider class also enables you to use other client-validation libraries by writing an adapter that processes the JSON data and calls into the alternate library.

New Code Snippets for Visual Studio 2010

A set of HTML code snippets for ASP.NET MVC 2 is installed with Visual Studio 2010. To view a list of these snippets, in the Tools menu, select Code Snippets Manager. For the language, select HTML, and for location, select ASP.NET MVC 2. For more information about how to use code snippets, see the Visual Studio documentation.

New RequireHttpsAttribute Action Filter

ASP.NET MVC 2 includes a new RequireHttpsAttribute class that can be applied to action methods and controllers. By default, the filter redirects a non-SSL (HTTP) request to the SSL-enabled (HTTPS) equivalent.

Overriding the HTTP Method Verb

When you build a Web site by using the REST architectural style, HTTP verbs are used to determine which action to perform for a resource. REST requires that applications support the full range of common HTTP verbs, including GET, PUT, POST, and DELETE.

ASP.NET MVC 2 includes new attributes that you can apply to action methods and that feature compact syntax. These attributes enable ASP.NET MVC to select an action method based on the HTTP verb. In the following example, a POST request will call the first action method and a PUT request will call the second action method.

```
[HttpPost]
public ActionResult Edit(int id)

[HttpPut]
public ActionResult Edit(int id, Tag tag)
```

In earlier versions of ASP.NET MVC, these action methods required more verbose syntax, as shown in the following example:

```
[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id)

[AcceptVerbs(HttpVerbs.Put)]
public ActionResult Edit(int id, Tag tag)
```

Because browsers support only the GET and POST HTTP verbs, it is not possible to post to an action that requires a different verb. Thus it is not possible to natively support all RESTful requests.

However, to support RESTful requests during POST operations, ASP.NET MVC 2 introduces a new HttpMethodOverride HTML helper method. This method renders a hidden input element that causes the form to effectively emulate any HTTP method. For example, by using the HttpMethodOverride HTML helper method, you can have a form submission appear be a PUT or DELETE request. The behavior of HttpMethodOverride affects the following attributes:

- HttpPostAttribute
- HttpPutAttribute
- HttpGetAttribute
- HttpDeleteAttribute
- AcceptVerbsAttribute

The hidden input element has its name X-HTTP-Method-Override and its value set to the HTTP verb to emulate. The override value can also be specified in an HTTP header or in a query string value as a name/value pair.

The override can only be used when the real request is a POST request. The override value will be ignored for requests that use any other HTTP verb.

New HiddenInputAttribute Class for Templated Helpers

You can apply the new HiddenInputAttribute attribute to a model property to indicate whether a hidden input element should be rendered when displaying the model in an editor template. (The attribute sets an implicit UIHint value of HiddenInput). The attribute's DisplayValue property lets you specify whether the value is displayed in editor and display modes. When DisplayValue is set to false, nothing is displayed, not even the HTML markup that normally surrounds a field. The default value for DisplayValue is true.

You might use HiddenInputAttribute attribute in the following scenarios:

- When a view lets users edit the ID of an object and it is necessary to display the value as well as to provide a hidden input element that contains the old ID so that it can be passed back to the controller.
- When a view lets users edit a binary property that should never be displayed, such as a timestamp property. In

that case, the value and surrounding HTML markup (such as the label and value) are not displayed.

The following example shows how to use the HiddenInputAttribute class.

```
public class ProductViewModel {
    [HiddenInput] // equivalent to [HiddenInput(DisplayValue=true)]
    public int Id { get; set; }

    public string Name { get; set; }

    [HiddenInput(DisplayValue=false)]
    public byte[] TimeStamp { get; set; }
}
```

When the attribute is set to true (or no parameter is specified), the following occurs:

- In display templates, a label is rendered and the value is displayed to the user.
- In editor templates, a label is rendered and the value is rendered in a hidden input element.

When the attribute is set to false, the following occurs:

- In display templates, nothing is rendered for that field.
- In editor templates, no label is rendered and the value is rendered in a hidden input element.

Html.ValidationSummary Helper Method Can Display Model-Level Errors

Instead of always displaying all validation errors, the Html.ValidationSummary helper method has a new option to display only model-level errors. This enables model-level errors to be displayed in the validation summary and field-specific errors to be displayed next to each field.

T4 Templates in Visual Studio Generate Code that is Specific to the Target Version of the .NET Framework

A new property is available to T4 files from the ASP.NET MVC T4 host that specifies the version of the .NET Framework that is used by the application. This enables T4 templates to generate code and markup that is specific to a version of the .NET Framework. In Visual Studio 2008, the value is always .NET 3.5. In Visual Studio 2010, the value is either .NET 3.5 or .NET 4.

API Improvements

This section describes changes to existing ASP.NET MVC types and members.

- Added a protected virtual CreateActionInvoker method in the Controller class. This method is invoked by the ActionInvoker property of Controller and allows for lazy instantiation of the invoker if no invoker is already set.
- Added a protected virtual HandleUnauthorizedRequest method in the AuthorizeAttribute class. This enables filters that derive from AuthorizeAttribute to control the behavior when authorization fails.
- Added an Add(string key, object value) method in the ValueProviderDictionary class. This enables you to use the dictionary initializer syntax for ValueProviderDictionary, as in the following example:

```
Controller c = new MyController();
c.ValueProvider = new ValueProviderDictionary(null) {
    { "example1", "example1Value" },
    { "example2", "example2Value" },
    { "example3", new int[] { 1, 2, 3 } }
};
```

- Added a get_object method in the Sys.Mvc.AjaxContext class. This is a JavaScript method that is similar to the get_data method, but if the content type of the response is application/json, get_object returns the JSON object.
- Added an ActionDescriptor property in the AuthorizationContext class.

- Added a UrlParameter.Optional token that can be used to work around problems when binding to a model that contains an ID property when the property is absent in a form post. For more detail, see the entry ASP.NET MVC 2 Optional URL Parameters on Phil Haack's blog.

Breaking Changes

The following changes might cause errors in existing ASP.NET MVC 1.0 applications.

Change in property validation behavior for classes that implement IDataErrorInfo

For model objects that use IDataErrorInfo to perform validation, every property is validated, regardless of whether a new value was set. In ASP.NET MVC 1.0, only properties that had new values set were validated. In ASP.NET MVC 2, the Error property of IDataErrorInfo is called only if all the property validators were successful.

IIS script mapping script is no longer available in the installer

The IIS script-mapping script is a command-line script that is used to configure script maps for IIS 6 and for IIS 7 in Classic mode. The script-mapping script is not needed if you use the Visual Studio Development Server or if you use IIS 7 in Integrated mode. The scripts are available as a separate unsupported download on the ASP.NET WebStack.

The Html.Substitute helper method in MVC Futures is no longer available

Due to changes in the rendering behavior of MVC view engines, the Html.Substitute helper method does not work and has been removed.

The IValueProvider interface replaces all uses of IDictionary

Every property or method argument that accepted IDictionary in MVC 1.0 now accepts IValueProvider. This change affects only applications that include custom value providers or custom model binders. Examples of properties and methods that are affected by this change include the following:

- The ValueProvider property of the ControllerBase and ModelBindingContext classes.
- The TryUpdateModel methods of the Controller class.

New CSS classes were added in the Site.css file

The Site.css file in the ASP.NET MVC project templates has been updated to include new styles used by the validation functionality and by the templated helpers.

Helpers now return an MvcHtmlString object

In order to take advantage of the new HTML-encoding expression syntax in ASP.NET 4, the return type for HTML helpers is now MvcHtmlString instead of a string. If you use ASP.NET MVC 2 and the new helpers on ASP.NET 3.5, you will not be able to take advantage of the HTML-encoding syntax; the new syntax is available only when you run ASP.NET MVC 2 on ASP.NET 4.

JsonResult now responds only to HTTP POST requests

In order to mitigate JSON hijacking attacks that have the potential for information disclosure, by default, the JsonResult class now responds only to HTTP POST requests. Ajax GET calls to action methods that return a JsonResult object should be changed to use POST instead. If necessary, you can override this behavior by setting the new JsonRequestBehavior property of JsonResult. For more information about the potential exploit, see the blog post JSON Hijacking on Phil Haack's blog.

Model and ModelType property setters on ModelBindingContext are obsolete

A new settable ModelMetadata property has been added to the ModelBindingContext class. The new property encapsulates both the Model and the ModelType properties. Although the Model and ModelType properties are obsolete, for backward compatibility the property getters still work; they delegate to the ModelMetadata property to retrieve the value.

Changes to the DefaultControllerFactory class break custom controller factories that derive from it

The DefaultControllerFactory class was fixed by removing the RequestContext property. In place of this property, the request context instance is passed to the protected virtual GetControllerInstance and GetControllerType

methods. This change affects custom controller factories that derive from DefaultControllerFactory.

Custom controller factories are often used to provide dependency injection for ASP.NET MVC applications. To update the custom controller factories to support ASP.NET MVC 2, change the method signature or signatures to match the new signatures, and use the request context parameter instead of the property.

"Area" is a now a reserved route-value key

The string "area" in Route values now has special meaning in ASP.NET MVC, in the same way that "controller" and "action" do. One implication is that if HTML helpers are supplied with a route-value dictionary containing "area", the helpers will no longer append "area" in the query string.

If you are using the Areas feature, make sure to not use {area} as part of your route URL.

ASP.NET MVC 3

2/20/2020 • 46 minutes to read • Edit Online

- Overview
- Installation Notes
- Software Requirements
- Documentation
- Support
- Upgrading an ASP.NET MVC 2 Project to ASP.NET MVC 3 Tools Update
- ASP.NET MVC 3 Tools Update (April 12, 2011)
  - "Add Controller" dialog box can now scaffold controllers with views and data access code
  - Improvements to the "ASP.NET MVC 3 New Project" Dialog Box
  - Project templates now include Modernizr 1.7
  - Project templates include updated versions of jQuery, jQuery UI, and jQuery Validation
  - Project templates now include ADO.NET Entity Framework 4.1 as a pre-installed NuGet package
  - Project templates include JavaScript libraries as pre-installed NuGet packages
  - Known Issues
- ASP.NET MVC 3 RTM (January 13, 2011)
  - Change: Updated the version of jQuery UI to 1.8.7
  - Change: Changed the default ModelMetadataProvider back to DataAnnotationsModelMetadataProvider
  - Fixed: Pasting part of a Razor expression that contains whitespace results in it being reversed
  - Fixed: Renaming a Razor file that is opened in the editor disables syntax colorization and IntelliSense
  - Known Issues
  - Breaking Changes
- ASP.NET MVC 3 Release Candidate 2 (December 10, 2010)
  - Project Templates Changed to Include jQuery 1.4.4, jQuery Validation 1.7, and jQuery UI 1.8.6y UI 1.8.6
  - Added "AdditionalMetadataAttribute" Class
  - Improved View Scaffolding
  - Added Html.Raw Method
  - Renamed "Controller.ViewModel" Property and the "View" Property To "ViewBag"
  - Renamed "ControllerSessionStateAttribute" Class to "SessionStateAttribute"
  - Renamed RemoteAttribute "Fields" Property to "AdditionalFields"
  - Renamed "SkipRequestValidationAttribute" to "AllowHtmlAttribute"
  - Changed "Html.ValidationMessage" Method to Display the First Useful Error Message
  - Fixed @model Declaration to not Add Whitespace to the Document
  - Added "FileExtensions" Property to View Engines to Support Engine-Specific File Names
  - Fixed "LabelFor" Helper to Emit the Correct Value for the "For" Attribute
  - Fixed "RenderAction" Method to Give Explicit Values Precedence During Model Binding
  - Breaking Changes

  - Known Issues
- ASP.NET MVC 3 Release Candidate (Nov 9, 2010)
  - New Features in ASP.NET MVC 3 RC
  - NuGet Package Manager
  - Improved "New Project" Dialog Box
  - Sessionless Controllers
  - New Validation Attributes
  - New Overloads for "LabelFor" and "LabelForModel" Methods
  - Child Action Output Caching
  - "Add View" Dialog Box Improvements
  - Granular Request Validation
  - Breaking Changes
  - Known Issues
- ASP.MVC 3 Beta Notes (Oct 6, 2010)
  - New Features in ASP.NET MVC 3 Beta
  - NuPack Package Manager
  - Improved New Project Dialog Box
  - Simplified Way to Specify Strongly Typed Models in Razor Views
  - Support for New ASP.NET Web Pages Helper Methods
  - Additional Dependency Injection Support
  - New Support for Unobtrusive jQuery-Based Ajax
  - New Support for Unobtrusive jQuery Validation
  - New Application-Wide Flags for Client Validation and Unobtrusive JavaScript
  - New Support for Code that Runs Before Views Run
  - New Support for the VBHTML Razor Syntax
  - More Granular Control over ValidateInputAttribute
  - Helpers Convert Underscores to Hyphens for HTML Attribute Names Specified Using Anonymous Objects
  - Bug Fixes
  - Breaking Changes
  - Known Issues
- Disclaimer

Overview

This document describes the release of ASP.NET MVC 3 RTM for Visual Studio 2010. ASP.NET MVC is a framework for developing Web applications that uses the Model-View-Controller (MVC) pattern. The ASP.NET MVC 3 installer includes the following components:

- ASP.NET MVC 3 runtime components
- ASP.NET MVC 3 Visual Studio 2010 tools
- ASP.NET Web Pages run-time components
- ASP.NET Web Pages Visual Studio 2010 tools
- Microsoft Package Manager for .NET (NuGet)
- An update for Visual Studio 2010 that enables support for Razor syntax. (For details, see KnowledgeBase article 2483190.)

The full set of release notes for each pre-release version of ASP.NET MVC 3 can be found on the ASP.NET website

at the following URL:

https://www.asp.net/learn/whitepapers/mvc3-release-notes

Installation Notes

To install ASP.NET MVC 3 RTM using the Web Platform Installer (Web PI), visit the following page:

https://www.microsoft.com/web/gallery/install.aspx?appid=MVC3

Alternatively, you can download the installer for ASP.NET MVC 3 RTM for Visual Studio 2010 from the following page:

https://go.microsoft.com/fwlink/?LinkID=208140

ASP.NET MVC 3 can be installed and can run side-by-side with ASP.NET MVC 2.

Software Requirements

The ASP.NET MVC 3 run-time components require the following software:

- .NET Framework version 4.

  ASP.NET MVC 3 Visual Studio 2010 tools require the following software:

- Visual Studio 2010 or Visual Web Developer 2010 Express.

Documentation

Documentation for ASP.NET MVC is available on the MSDN Web site at the following URL:

https://go.microsoft.com/fwlink/?LinkId=205717

Tutorials and other information about ASP.NET MVC are available on the MVC page of the ASP.NET Web site at the following URL:

https://www.asp.net/mvc/

Support

This is a fully supported release. Information about getting technical support can be found at the Microsoft Support website.

Also feel free to post questions about this release to the ASP.NET MVC forum, where members of the ASP.NET community are frequently able to provide informal support:

https://forums.asp.net/1146.aspx

Upgrading an ASP.NET MVC 2 Project to ASP.NET MVC 3 Tools Update

ASP.NET MVC 3 can be installed side by side with ASP.NET MVC 2 on the same computer, which gives you flexibility in choosing when to upgrade an ASP.NET MVC 2 application to ASP.NET MVC 3.

To manually upgrade an existing ASP.NET MVC 2 application to version 3, do the following:

1. Create a new empty ASP.NET MVC 3 project on your computer. This project will contain some files that are required for the upgrade.

2. Copy the following files from the ASP.NET MVC 3 project into the corresponding location of your ASP.NET MVC 2 project. You'll need to update any references to the jQuery library to account for the new filename

(jQuery-1.5.1.js):

- /Views/Web.config
- /packages.config
- /scripts/*.js
- /Content/themes/*.*

3. Copy the *packages* folder in the root of the empty ASP.NET MVC 3 project solution into the root of your solution, which is in the directory where the solution's .sln file is located.

4. If your ASP.NET MVC 2 project contains any areas, copy the /Views/Web.config file to the *Views* folder of each area.

5. In both Web.config files in the ASP.NET MVC 2 project, globally search and replace the ASP.NET MVC version. Find the following:

   ```
   System.Web.Mvc, Version=2.0.0.0
   ```

   Replace it with the following:

   ```
   System.Web.Mvc, Version=3.0.0.0
   ```

6. In Solution Explorer, delete the reference to *System.Web.Mvc* (which points to the DLL from version 2), then add a reference to *System.Web.Mvc* (v3.0.0.0).

7. Add a reference to System.Web.WebPages.dll and System.Web.Helpers.dll. These assemblies are located in the following folders:

   - %ProgramFiles%\ Microsoft ASP.NET\ASP.NET MVC 3\Assemblies
   - %ProgramFiles%\ Microsoft ASP.NET\ASP.NET Web Pages\v1.0\Assemblies

8. In Solution Explorer, right-click the project name and select Unload Project. Then right-click the project name again and select Edit *ProjectName*.csproj.

9. Locate the *ProjectTypeGuids* element and replace {F85E285D-A4E0-4152-9332-AB1D724D3325} with {E53F8FEA-EAE0-44A6-8774-FFD645390401}.

10. Save the changes, right-click the project, and then select Reload Project.

11. In the application's root Web.config file, add the following settings to the *assemblies* section.

    ```
    <add assembly="System.Web.WebPages, Version=1.0.0.0, Culture=neutral,
         PublicKeyToken=31BF3856AD364E35" />

    <add assembly="System.Web.Helpers, Version=1.0.0.0, Culture=neutral,
         PublicKeyToken=31BF3856AD364E35" />
    ```

12. If the project references any third-party libraries that are compiled using ASP.NET MVC 2, add the following highlighted *bindingRedirect* element to the Web.config file in the application root under the *configuration* section:

```
<runtime>
   <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
     <dependentAssembly>
       <assemblyIdentity name="System.Web.Mvc"
           publicKeyToken="31bf3856ad364e35"/>
       <bindingRedirect oldVersion="1.0.0.0-2.0.0.0" newVersion="3.0.0.0"/>
     </dependentAssembly>
   </assemblyBinding>
</runtime>
```

Changes in ASP.NET MVC 3 Tools Update

This section describes changes made in the ASP.NET MVC 3 Tools Update release since the ASP.NET MVC 3 RTM release.

"Add Controller" dialog box can now scaffold controllers with views and data access code

Scaffolding is a way of quickly generating a controller and views for your application. After the code has been generated, you can edit it to meet your project's requirements.

To launch the *Add Controller* dialog box in ASP.NET MVC 3, right-click the *Controllers* folder in *Solution Explorer*, click *Add*, and then click *Controller*. The dialog box has been enhanced to offer additional scaffolding options.

There are three scaffolding templates available by default.

Empty Controller

This template generates an empty controller file. This template is equivalent to not checking *Add actions for create, edit, details, delete scenarios* in previous versions of ASP.NET MVC. If you choose this, no further options are available.

Controller with empty read/write actions

This template generates a controller file that has all the required action methods but no implementation code in the methods. This template is equivalent to checking *Add actions for create, edit, details, delete scenarios* in previous versions of ASP.NET MVC. If you choose this, no further options are available.

Controller with read/write actions and views, using Entity Framework

This template enables you to quickly create a working data-entry user interface. It generates code that handles a range of common requirements and scenarios, such as the following:

- *Data access*. The generated code reads and writes entities in a database. It works with the Entity Framework Code First approach if you choose an existing data context class or if you let the template generate a new *DbContext* class. It also works with the Entity Framework Database First or Model First approach if you choose an existing *ObjectContext* class.
- *Validation*. The generated code uses ASP.NET MVC model binding and metadata features so that form submissions are validated according to rules declared on your model class. This includes built-in validation rules, such as the *Required* and *StringLength* attributes, and custom validation rules.
- *One-to-many relationships*. If you define one-to-many foreign-key relationships between your model classes, the generated code will produce drop-down lists for selecting related entities. For example, you might define the following model classes following Entity Framework Code First conventions:

```
public class Product
{
     public int ProductId { get; set; }
     [Required]
     public string Name { get; set; }

     // Product belongs to Category
     public int CategoryId { get; set; }
     public virtual Category Category { get; set; }
}
public class Category
{
     public int CategoryId { get; set; }
     [Required]
     public string Name { get; set; }
}
```

  When you then scaffold a controller for the *Product* class, its views will allow users to choose a *Category* object for each *Product* instance.

  This template enables additional options in the *Add Controller* dialog box. For *Model class*, you can choose any model class in your solution, which determines the type of data that users will be able to create or edit:

- If you want to use Entity Framework Code First, you can choose any model class.
- If you are using Entity Framework Database First or Entity Framework Model First, be sure to choose an entity class defined in your conceptual model.

For *Data Context class*, you can make these choices:

- If you want to use Code First and have no existing data context class, choose **New data context **. A data context class will then be generated for you.
- If you want to use Code First and have an existing data context class, choose it here. It will be updated to persist the model class you have selected.
- If you are using Database First or Model First, choose your object context class here.

For Views, choose the view engine you want to use, or choose None if you don't want to scaffold any views.

You can select Advanced Optionsto specify further options for the generated views. For example, you can choose the layout or master page to use.

Improvements to the "ASP.NET MVC 3 New Project" Dialog Box

The dialog box you use to create new ASP.NET MVC 3 projects includes multiple improvements, as listed below.

New "Intranet Project" Template

The Project Template list includes a new Intranet Application template. This template contains settings for building a web application using Windows authentication instead of forms authentication. Because an intranet application requires some IIS settings that can't be encapsulated in a project template, the template includes a readme file with instructions for how to make the project template work in IIS. Documentation for the a new Intranet Application template is available on the MSDN website at the following URL:

https://msdn.microsoft.com/library/gg703322(VS.98).aspx

Project templates are now HTML5 enabled

The new-project dialog box now contains an option to add HTML5-specific features to the project templates. Selecting the option causes views to be generated that contain the new HTML5 `<header>`, `<footer>`, and `<navigation>` elements.

Note that earlier versions of browsers do not support HTML5-specific tags. To address this limitation, the HTML5 project templates include a reference to the Modernizr library. (See the next section.)

Project templates now include Modernizr 1.7

Modernizr is a JavaScript library that enables support for CSS 3 and HTML5 in browsers that do not yet support these features. This library is included as a pre-installed NuGet package in templates for ASP.NET MVC 3 projects. For more information about Modernizr, see http://www.modernizr.com/.

Project templates include updated versions of jQuery, jQuery UI, and jQuery Validation

The project templates now include the following versions of the jQuery scripts:

- jQuery 1.5.1
- jQuery Validation 1.8
- jQuery UI 1.8.11

These libraries are included as pre-installed NuGet packages.

Project templates now include ADO.NET Entity Framework 4.1 as a pre-installed NuGet package

The ADO.NET Entity Framework 4.1 includes the Code First feature. Code First is a new development pattern for the ADO.NET Entity Framework that provides an alternative to the existing Database First and Model First patterns.

Code First is focused around defining your model using POCO classes ("plain old CLR objects") written in Visual Basic or C#. These classes can then be mapped to an existing database or be used to generate a database schema. Additional configuration can be supplied using *DataAnnotations* attributes or using fluent APIs.

Documentation for using Code Firstwith ASP.NET MVC is available on the ASP.NET website at the following URLs:

https://www.asp.net/mvc/tutorials/getting-started-with-mvc3-part1-cs https://www.asp.net/entity-framework/tutorials/creating-an-entity-framework-data-model-for-an-asp-net-mvc-application

Project templates include JavaScript libraries as pre-installed NuGet packages

When you create a new ASP.NET MVC 3 project, the project includes the JavaScript files mentioned previously (for example, the Modernizr library) by installing them using NuGet instead of directly adding the scripts to the Scripts folder in the project template contents. This enables you to use NuGet to update the scripts to the latest version when new versions of the scripts are released.

For example, given the frequency of new jQuery releases, the version of jQuery included in the project template will at some point be out of date. However, because jQuery is included as an installed NuGet package, you will be notified in the NuGet dialog box when newer versions of jQuery are available.

Because jQuery includes the version number in the file name, updating jQuery to the latest version also requires updating the `<script>` tag that references the jQuery file to use the new file name. Other included script libraries do not include the version number in the script name, so they can be more easily updated to their latest versions.

Known Issues

- In some cases, installation may fail with the error message "Installation failed with error code (0x80070643)". For information about how to work around this issue, see KnowledgeBase article 2531566.
- The scaffolding for adding a controller does not scaffold entities that take advantage of entity inheritance support within Entity Framework. For example, given a base *Person* class that's inherited by a *Student* class, scaffolding the *Student* class will result in generated code that does not compile.
- Creating a new ASP.NET MVC 3 project within a solution folder causes a *NullReferenceException* error. The workaround is to create the ASP.NET MVC 3 project in the root of the solution and then move it into the solution folder.
- IntelliSense for Razor syntax does not work when ReSharper is installed. If you have ReSharper installed and want to take advantage of the Razor IntelliSense support in ASP.NET MVC 3, see the entry Razor Intellisense and ReSharper on Hadi Hariri's blog, which discusses ways to use them together today.
- During installation, the EULA acceptance dialog box displays the license terms in a window that is smaller than intended.
- When you are editing a Razor view (.cshtml or *.vbhtml* file), views. ASP.NET MVC 3 does not include any snippets for Razor views..aspxselecting a code snippet for ASP.NET MVC will show snippets for
- If you install ASP.NET MVC 3 for Visual Web Developer Express on a computer where Visual Studio is not installed, and then later install Visual Studio, you must reinstall ASP.NET MVC 3. Visual Studio and Visual Web Developer Express share components that are upgraded by the ASP.NET MVC 3 installer. The same issue applies if you install ASP.NET MVC 3 for Visual Studio on a computer that does not have Visual Web Developer Express and then later install Visual Web Developer Express.

Changes in ASP.NET MVC 3 RTM

This section describes changes and bug fixes made in the ASP.NET MVC 3 RTM release since the RC2 release.

Change: Updated the version of jQuery UI to 1.8.7

The ASP.NET MVC project templates for Visual Studio were updated to include the latest version of the jQuery UI library. The templates also include the minimal set of resource files required by jQuery UI, such as the associated CSS and image files.

Change: Changed the default ModelMetadataProvider back to DataAnnotationsModelMetadataProvider

The RC2 release of ASP.NET MVC 3 introduced a *CachedDataAnnotationsMetadataProvider* class that provided caching on top of the existing *DataAnnotationsModelMetadataProvider* class as a performance improvement. However, some bugs were reported with this implementation, so the change has been reverted and moved into the MVC Futures project, which is available at ASP.NET WebStack.

Fixed: Pasting part of a Razor expression that contains whitespace results in it being reversed

In pre-release versions of ASP.NET MVC 3, when you paste a part of a Razor expression that contains whitespace into a Razor file, the resulting expression is reversed. For example, consider the following Razor code block:

```
@SomeMethod("first param",
100)
@AnotherMethod()
```

If you select the text "first param" in the first method and paste it as an argument into the second method, the result is as follows:

```
@AnotherMethod(param""first)
```

The correct behavior is that the paste operation should result in the following:

```
@AnotherMethod("first param")
```

This issue has been fixed in the RTM release so that the expression is correctly preserved during the paste operation.

Fixed: Renaming a Razor file that is opened in the editor disables syntax colorization and IntelliSense

Renaming a Razor file using Solution Explorer while the file is opened in the editor window causes syntax highlighting and IntelliSense to stop working for that file. This has been fixed so that highlighting and IntelliSense are maintained after a rename.

Known Issues

- If you close Visual Studio 2010 SP1 Beta while the NuGet Package Manager Console is open, Visual Studio crashes and attempts to restart. This will be fixed in the RTM release of Visual Studio 2010 SP1.
- The ASP.NET MVC 3 installer is only able to install an initial version of the NuGet package manager. After you have installed the initial version, NuGet can be installed and updated using Visual Studio Extension Manager. If you already have NuGet installed, go to the Visual Studio Extension Gallery to update to the latest version of NuGet.
- Creating a new ASP.NET MVC 3 project within a solution folder causes a *NullReferenceException* error. The workaround is to create the ASP.NET MVC 3 project in the root of the solution and then move it into the solution folder.
- The installer might take much longer than previous versions of ASP.NET MVC to complete. This is because it

updates components of Visual Studio 2010.

- IntelliSense for Razor syntax does not work when ReSharper is installed. If you have ReSharper installed and want to take advantage of the Razor IntelliSense support in ASP.NET MVC 3, see the entry Razor Intellisense and ReSharper on Hadi Hariri's blog, which discusses ways to use them together today.
- CCSHTML and VBHTML views created with the Beta version of ASP.NET MVC 3 do not have their build action set correctly, with the result that these view types are omitted when the project is published. The Build Action value for these files should be set to "Content". ASP.NET MVC 3 RTM fixes this issue for new files, but doesn't correct the setting for existing files for a project created with prerelease versions.

-
- During installation, the EULA acceptance dialog box displays the license terms in a window that is smaller than intended.
- When you are editing a Razor view (.cshtml file), the Go To Controller menu item in Visual Studio will not be available, and there are no code snippets.
- If you install ASP.NET MVC 3 for Visual Web Developer Express on a computer where Visual Studio is not installed, and then later install Visual Studio, you must reinstall ASP.NET MVC 3. Visual Studio and Visual Web Developer Express share components that are upgraded by the ASP.NET MVC 3 installer. The same issue applies if you install ASP.NET MVC 3 for Visual Studio on a computer that does not have Visual Web Developer Express and then later install Visual Web Developer Express.

Breaking Changes

- In previous versions of ASP.NET MVC, action filters are create per request except in a few cases. This behavior was never a guaranteed behavior but merely an implementation detail and the contract for filters was to consider them stateless. In ASP.NET MVC 3, filters are cached more aggressively. Therefore, any custom action filters which improperly store instance state might be broken.
- The order of execution for exception filters has changed for exception filters that have the same *Order* value. In ASP.NET MVC 2 and earlier, exception filters on the controller that have the same *Order* value as those on an action method are executed before the exception filters on the action method. This would typically be the case when exception filters are applied without a specified *Order* value. In ASP.NET MVC 3, this order has been reversed so that the most specific exception handler executes first. As in earlier versions, if the *Order* property is explicitly specified, the filters are run in the specified order.
- A new property named *FileExtensions* was added to the *VirtualPathProviderViewEngine* base class. When ASP.NET looks up a view by path (not by name), only views with a file extension contained in the list specified by this new property are considered. This is a breaking change in applications where a custom build provider is registered in order to enable a custom file extension for Web Form views and where the provider

references those views by using a full path rather than a name. The workaround is to modify the value of the *FileExtensions* property to include the custom file extension.

- Custom controller factory implementations that directly implement the *IControllerFactory* interface must provide an implementation of the new *GetControllerSessionBehavior* method that was added to the interface in this release. In general, it is recommended that you do not implement this interface directly and instead derive your class from *DefaultControllerFactory*.

Changes in ASP.NET MVC 3 RC2

This section describes changes (new features and bug fixes) made in the ASP.NET MVC 3 RC2 release since the RC release.

Project Templates Changed to Include jQuery 1.4.4, jQuery Validation 1.7, and jQuery UI 1.8.6

The project templates for ASP.NET MVC 3 now include the latest versions of jQuery, jQuery Validation, and jQuery UI. jQuery UI is a new addition to the project templates and provides useful user interface widgets. For more information about jQuery UI, visit their homepage: http://jqueryui.com/.

Added "AdditionalMetadataAttribute" Class

You can use the *AdditionalMetadataAttribute* class to populate the *ModelMetadata.AdditionalValues* dictionary for a model property.

For example, suppose a view model has properties that should be displayed only to an administrator. That model can be annotated with the new attribute using AdminOnly as the key and true as the value, as in the following example:

```
public class ProductViewModel {
    [AdditionalMetadata("AdminOnly", true)]
    public string RefundCode {get; set;}
}
```

This metadata is made available to any display or editor template when a product view model is rendered. It is up to you as application developer to interpret the metadata information.

Improved View Scaffolding

The T4 templates used for scaffolding views now generate calls to template helper methods such as *EditorFor* instead of helpers such as *TextBoxFor*. This change improves support for metadata on the model in the form of data annotation attributes when the Add View dialog box generates a view.

The Add View scaffolding also includes improved detection and usage of primary key information on the model, based on convention. For example, the Add View dialog box uses this information to ensure that the primary key value is not scaffolded as an editable form field.

The default Edit and Create templates include references to the jQuery scripts needed for client validation.

Added Html.Raw Method

By default, the Razor view engine HTML-encodes all values. For example, the following code snippet encodes the HTML inside the greeting variable so that it is displayed in the page as `<strong>Hello World!</strong>`.

```
@{
  string greeting = "<strong>Hello World!</strong>";
}

<p>@greeting</p>
```

The new *Html.Raw* method provides a simple way of displaying unencoded HTML when the content is known to

be safe. The following example displays the same string, but the string is rendered as markup:

```
@{
  string greeting = "<strong>Hello World!</strong>";
}

<p>@Html.Raw(greeting)</p>
```

Renamed "Controller.ViewModel" Property and the "View" Property To "ViewBag"

Previously, the *ViewModel* property of *Controller* corresponded to the *View* property of a view. Both of these properties provide a way to access values of the *ViewDataDictionary* object using dynamic property-accessor syntax. Both properties have been renamed to be the same in order to avoid confusion and to be more consistent.

Renamed "ControllerSessionStateAttribute" Class to "SessionStateAttribute"

The *ControllerSessionStateAttribute* class was introduced in the RC release of ASP.NET MVC 3. The property was renamed to be more succinct.

Renamed RemoteAttribute "Fields" Property to "AdditionalFields"

The *RemoteAttribute* class's *Fields* property caused some confusion among users. Renaming this property to *AdditionalFields* clarifies its intent.

Renamed "SkipRequestValidationAttribute" to "AllowHtmlAttribute"

The *SkipRequestValidationAttribute* attribute was renamed to *AllowHtmlAttribute* to better represent its intended usage.

Changed "Html.ValidationMessage" Method to Display the First Useful Error Message

The *Html.ValidationMessage* method was fixed to show the first useful error message instead of simply displaying the first error.

During model binding, the *ModelState* dictionary can be populated from multiple sources with error messages about the property, including from the model itself (if it implements *IValidatableObject*), from validation attributes applied to the property, and from exceptions thrown while the property is being accessed.

When the *Html.ValidationMessage* method displays a validation message, it skips model-state entries that include an exception, because these are generally not intended for the end user. Instead, the method looks for the first validation message that is not associated with an exception and displays that message. If no such message is found, it defaults to a generic error message that is associated with the first exception.

Fixed @model Declaration to not Add Whitespace to the Document

In earlier releases, the `@model` declaration at the top of a view added a blank line to the rendered HTML output. This has been fixed so that the declaration does not introduce whitespace.

Added "FileExtensions" Property to View Engines to Support Engine-Specific File Names

A view engine can return a view using an explicit view path as in the following example:

```
return View("~/views/home/index.cshtml");
```

The first view engine always attempts to render the view. By default, the Web Forms view engine is the first view engine; because the Web Forms engine cannot render a Razor view, an error occurs. View engines now have a *FileExtensions* property that is used to specify which file extensions they support. This property is checked when ASP.NET determines whether a view engine can render a file. This is a breaking change and more details are included in the Breaking Changes section of this document.

Fixed "LabelFor" Helper to Emit the Correct Value for the "For" Attribute

A bug was fixed where the *LabelFor* method rendered a *for* attribute that matches the *input* element's *name* attribute instead of its ID. According to the W3C, the *for* attribute should match the *input* element's ID.

Fixed "RenderAction" Method to Give Explicit Values Precedence During Model Binding

In earlier versions, explicit values that were passed to the *RenderAction* method were being ignored in favor of the current form values during model binding inside a child action. The fix ensures that explicit values take precedence during model binding.

Breaking Changes

- In previous versions of ASP.NET MVC, action filters were created per request except in a few cases. This behavior was never a guaranteed behavior but merely an implementation detail and the contract for filters was to consider them stateless. In ASP.NET MVC 3, filters are cached more aggressively. Therefore, any custom action filters which improperly store instance state might be broken.
- The order of execution for exception filters has changed for exception filters that have the same *Order* value. In ASP.NET MVC 2 and earlier, exception filters on the controller that had the same *Order* value as those on an action method were executed before the exception filters on the action method. This would typically be the case when exception filters were applied without a specified *Order* value. In ASP.NET MVC 3, this order has been reversed so that the most specific exception handler executes first. As in earlier versions, if the *Order* property is explicitly specified, the filters are run in the specified order.
- A new property named *FileExtensions* was added to the *VirtualPathProviderViewEngine* base class. When ASP.NET looks up a view by path (not by name), only views with a file extension contained in the list specified by this new property are considered. This is a breaking change in applications where a custom build provider is registered in order to enable a custom file extension for Web Form views and where the provider references those views by using a full path rather than a name. The workaround is to modify the value of the *FileExtensions* property to include the custom file extension.
- Custom controller factory implementations that directly implement the *IControllerFactory* interface must provide an implementation of the new *GetControllerSessionBehavior* method that was added to the interface in this release. In general, it is recommended that you do not implement this interface directly and instead derive your class from *DefaultControllerFactory*.

Known Issues

- The ASP.NET MVC 3 installer is only able to install an initial version of the NuGet package manager. After you have installed the initial version, NuGet can be installed and updated using Visual Studio Extension Manager. If you already have NuGet installed, go to the Visual Studio Extension Gallery to update to the latest version of NuGet.
- Creating a new ASP.NET MVC 3 project within a solution folder causes a *NullReferenceException* error. The workaround is to create the ASP.NET MVC 3 project in the root of the solution and then move it into the solution folder.
- The installer might take much longer than previous versions of ASP.NET MVC to complete. This is because it updates components of Visual Studio 2010.
- IntelliSense for Razor syntax does not work when ReSharper is installed. If you have ReSharper installed and want to take advantage of the Razor IntelliSense support in ASP.NET MVC 3 RC2, see the entry Razor Intellisense and ReSharper on Hadi Hariri's blog, which discusses ways to use them together today.
- CSHTML and VBHTML views created with the Beta version of ASP.NET MVC 3 do not have their build action set correctly, with the result that these view types are omitted when the project is published. The *Build Action* value for these files should be set to Content". ASP.NET MVC 3 RC2 fixes this issue for new files, but doesn't correct the setting for existing files for a project created with the Beta version.

- During installation, the EULA acceptance dialog box displays the license terms in a window that is smaller than intended.
- When you are editing a Razor view (.cshtml file), the Go To Controller menu item in Visual Studio will not be available, and there are no code snippets.
- If you install ASP.NET MVC 3 for Visual Web Developer Express on a computer where Visual Studio is not installed, and then later install Visual Studio, you must reinstall ASP.NET MVC 3. Visual Studio and Visual Web Developer Express share components that are upgraded by the ASP.NET MVC 3 installer. The same issue applies if you install ASP.NET MVC 3 for Visual Studio on a computer that does not have Visual Web Developer Express and then later install Visual Web Developer Express.
- Installing ASP.NET MVC 3 RC 2 does not update NuGet if you already have it installed. To upgrade NuGet, go to the Visual Studio Extension manager and it should show up as an available update. You can upgrade NuGet to the latest release from there.

ASP.NET MVC 3 Release Candidate

ASP.NET MVC Release Candidate was released on November 9, 2010.

New Features in ASP.NET MVC 3 RC

This section describes features that have been introduced in the ASP.NET MVC 3 RC release since the Beta release.

NuGet Package Manager

ASP.NET MVC 3 includes the NuGet Package Manager (formerly known as NuPack), which is an integrated package management tool for adding libraries and tools to Visual Studio projects. This tool automates the steps that developers take today to get a library into their source tree.

You can work with NuGet as a command-line tool, as an integrated console window inside Visual Studio 2010, from the Visual Studio context menu, and as a set of PowerShell cmdlets.

For more information about NuGet, read the Nuget Documentation.

Improved "New Project" Dialog Box

When you create a new project, the New Project dialog box now lets you specify the view engine as well as an ASP.NET MVC project type.

Support for modifying the list of templates and view engines listed in the dialog box is included in this release.

The default templates are the following:

Empty. Contains a minimal set of files for an ASP.NET MVC project, including the default directory structure for ASP.NET MVC projects, a Site.css file that contains the default ASP.NET MVC styles, and a Scripts directory that contains the default JavaScript files.

Internet Application. Contains sample functionality that demonstrates how to use the membership provider with ASP.NET MVC.

The list of project templates that is displayed in the dialog box is specified in the Windows registry.

Sessionless Controllers

The new *ControllerSessionStateAttribute* gives you more control over session-state behavior for controllers by specifying a System.Web.SessionState.SessionStateBehavior enumeration value.

The following example shows how to turn off session state for all requests to a controller.

```
[ControllerSessionState(SessionStateBehavior.Disabled)]
public class CoolController : Controller {
    public ActionResult Index() {
        object o = Session["Key"]; // Causes an exception.

    }
}
```

The following example shows how to set read-only session state for all requests to a controller.

```
[ControllerSessionState(SessionStateBehavior.ReadOnly)]
public class CoolController : Controller {
    public ActionResult Index() {
    Session["Key"] = "value"; // Value is not available in
    the next request
    }
}
```

New Validation Attributes

CompareAttribute

The new *CompareAttribute* validation attribute lets you compare the values of two different properties of a model. In the following example, the *ComparePassword* property must match the *Password* field in order to be valid.

```
public class User {
    [Required]

    public string Password { get; set; }
    [Required, Compare("Password")]
    public string ComparePassword { get; set; }
}
```

RemoteAttribute

The new *RemoteAttribute* validation attribute takes advantage of the jQuery Validation plug-in's remote validator, which enables client-side validation to call a method on the server that performs the actual validation logic.

In the following example, the *UserName* property has the *RemoteAttribute* applied. When editing this property in an Edit view, client validation will call an action named *UserNameAvailable* on the *UsersController* class in order to validate this field.

```
public class User {
    [Remote("UserNameAvailable", "Users")]
    public string UserName { get; set; }
}
```

The following example shows the corresponding controller.

```
public class UsersController {
    public bool UserNameAvailable(string username) {
        if(MyRepository.UserNameExists(username)) {
            return "false";
        }
        return "true";
    }
}
```

By default, the property name that the attribute is applied to is sent to the action method as a query-string parameter.

New Overloads for "LabelFor" and "LabelForModel" Methods

New overloads have been added for the *LabelFor* and *LabelForModel* methods that let you specify the label text. The following example shows how to use these overloads.

```
@Html.LabelFor(m => m.PropertyName,
"Label Text");
@Html.LabelForModel("Label Text");
```

Child Action Output Caching

The *OutputCacheAttribute* supports output caching of child actions that are called by using the *Html.RenderAction* or *Html.Action* helper methods. The following example shows a view that calls another action.

```
Hi there. The uncached time is:
@DateTime.Now
The cached time is: @Html.Action("GetDate")
```

The *GetDate* action is annotated with the *OutputCacheAttribute*:

```
[OutputCache(Duration = 100,
VaryByParam = "none")]
public string GetDate() {
    return DateTime.Now.ToString();
}
```

When this code runs, the result of the call to Html.Action("GetDate") is cached for 100 seconds.

"Add View" Dialog Box Improvements

When you add a strongly typed view, the Add View dialog box now filters out more non-applicable types than in previous releases, such as many core .NET Framework types. Also, the list is now sorted by the class name and not by the fully qualified type name, which makes it easier to find types. For example, the type name is now displayed as in the following example:

ClassName (namespace)

In earlier releases, this would have been displayed as the following:

Namespace.ClassName

Granular Request Validation

The *Exclude* property of *ValidateInputAttribute* no longer exists. Instead, to have request validation skipped for specific properties of a model during model binding, use the new *SkipRequestValidationAttribute*.

For example, suppose an action method is used to edit a blog post:

```
[HttpPost]
public ActionResult Edit(BlogPostViewModel post) {
    // Save the post in the database
}
```

The following example shows the view model for a blog post.

```
public class BlogPostViewModel {
    public int Id {get; set;}

    public string Subject {get; set;}

    public string Description {get; set;}
}
```

When a user submits some markup for the Description property, model binding will fail due to request

validation. To disable request validation during model binding for the blog post Description, apply the *SkipRequpestValidationAttribute* to the property, as shown in this example:.

```
public class BlogPostViewModel {
    public int Id {get; set;}

    public string Subject {get; set;}

    [SkipRequestValidation]

    public string Description {get; set;}
}
```

Alternatively, to turn off request validation for every property of the model, apply *ValidateInputAttribute* with a value of *false* to the action method:

```
[HttpPost]
[ValidateInput(false)]
public ActionResult Edit(BlogPostViewModel post) {
    // Save the post in the database
}
```

Breaking Changes

- The order of execution for exception filters has changed for exception filters that have the same *Order* value. In ASP.NET MVC 2 and earlier, exception filters on the controller that had the same *Order* as those on an action method were executed before the exception filters on the action method. This would typically be the case when exception filters were applied without a specified *Order* value. In ASP.NET MVC 3, this order has been reversed so that the most specific exception handler executes first. As in earlier versions, if the *Order* property is explicitly specified, the filters are run in the specified order.
- Added a new property named *FileExtensions* to the *VirtualPathProviderViewEngine* base class. When looking up a view by path (and not by name), only views with a file extension contained in the list specified by this new property is considered. This is a breaking change for those who register a custom build provider to enable a custom file extension for web form views and are referencing those views by using a full path rather than a name. The workaround is to modify the value of the *FileExtensions* property to include the custom file extension.

Known Issues

- The installer may take much longer than previous versions of ASP.NET MVC to complete because it updates components of Visual Studio 2010.
- The Add View scaffolding when selecting astrongly typed view scaffolds write-only properties. These should always be ignored by scaffolding. The Add View dialog also scaffolds read-only properties when generating an "Edit" or "Create" view. Read-only properties should only be scaffolded for the Display and List views.
- Debugging doesn't work when ASP.NET MVC 3 is installed alongside the Async CTP. ASP.NET MVC 3 cannot be installed side-by-side with the Async CTP. Uninstall the Async CTP to repair debugging. For more details, read this blog post about uninstalling all the pieces of ASP.NET MVC 3 RC.
- Razor Intellisense does not work when Resharper is installed. If you have ReSharper installed and want to take advantage of the Razor intellisense support in ASP.NET MVC 3 RC, please read this blog post from JetBrains which discusses ways to use them together today.
- CSHTML and VBHTML views created with Beta of ASP.NET MVC 3 do not have their build action correctly which omits them from publishing. The *Build Action* for these files should be set to "Content". ASP.NET MVC 3 RC fixes this issue for new files, but doesn't correct the setting for existing files for a project created with the

Beta.

- The installer may take much longer than previous versions of ASP.NET MVC to complete because it updates components of Visual Studio 2010.
- The Add View scaffolding when selecting an "Edit" strongly typed view scaffolds read only properties. Likewise, write-only properties are scaffolded for "Display" views.
- During installation, the EULA acceptance dialog box displays the license terms in a window that is smaller than intended.
- Installing the Visual Studio Async CTP causes a conflict with the Razor release that is included as part of the ASP.NET MVC 3 tooling installation. Make sure that you do not try to install both the Visual Studio Async CTP and the Razor release on the same machine.
- When you are editing a Razor view (.cshtml file), the Go To Controller menu item in Visual Studio will not be available, and there are no code snippets.

ASP.NET MVC 3 Beta

ASP.NET MVC 3 Beta was released on October 6, 2010. The following notes are specific to the Beta release, and are subject to any updates or changes referenced in the ASP.NET MVC 3 Release Candidate section above.

New Featuresin ASP.NET MVC 3 Beta

This section describes features that have been introduced in the ASP.NET MVC 3 Beta release.

NuGet Package Manager

ASP.NET MVC 3 includes NuGet Package Manager, which is an integrated package management tool for adding libraries and tools to Visual Studio projects. For the most part, it automates the steps that developers take today to get a library into their source tree.

You can work with NuGet as a command line tool, as an integrated console window inside Visual Studio 2010, from the Visual Studio context menu, and as set of PowerShell cmdlets.

For more information about NuGet, read the NuGet Documentation.

Improved New Project Dialog Box

When you create a new project, the New Project dialog box now lets you specify the view engine as well as an ASP.NET MVC project type.

Support for modifying the list of templates and view engines listed in the dialog box is not included in this release.

The default templates are the following:

Empty. Contains a minimal set of files for an ASP.NET MVC project, including the default directory structure for ASP.NET MVC projects, a small Site.css file that contains the default ASP.NET MVC styles, and a Scripts directory that contains the default JavaScript files.

Internet Application. Contains sample functionality that demonstrates how to use the membership provider within ASP.NET MVC.

Simplified Way to Specify Strongly Typed Models in Razor Views

The way to specify the model type for strongly typed Razor views has been simplified by using the new @model directive for CSHTML views and @ModelType directive for VBHTML views. In earlier versions of ASP.NET MVC, you would specify a strongly typed model for Razor views this way:

```
@inherits System.Web.Mvc.WebViewPage
```

In this release, you can use the following syntax:

```
@model MyModelNamespace.MyModelType
```

Support for New ASP.NET Web Pages Helper Methods

The new ASP.NET Web Pages technology includes a set of helper methods that are useful for adding commonly used functionality to views and controllers. ASP.NET MVC 3 supports using these helper methods within controllers and views (where appropriate). These methods are contained in the System.Web.Helpers assembly.

The following table lists a few of the ASP.NET Web Pages helper methods.

HELPER	DESCRIPTION
Chart	Renders a chart within a view. Contains methods such as Chart.ToWebImage, Chart.Save, and Chart.Write.
Crypto	Uses hashing algorithms to create properly salted and hashed passwords.
WebGrid	Renders a collection of objects (typically, data from a database) as a grid. Supports paging and sorting.
WebImage	Renders an image.
WebMail	Sends an email message.

A quick reference topic that lists the helpers and basic syntax is available as part of the ASP.NET Razor syntax documentation at the following URL:

https://www.asp.net/webmatrix/tutorials/asp-net-web-pages-api-reference

Additional Dependency Injection Support

Building on the ASP.NET MVC 3 Preview 1 release, the current release includes added support for two new services and four existing services, and improved support for dependency resolution and the Common Service Locator.

New IControllerActivator Interface for Fine-Grained Controller Instantiation

The new IControllerActivator interface provides more fine-grained control over how controllers are instantiated via dependency injection. The following example shows the interface:

```
namespace System.Web.Mvc {
    using System.Web.Routing;

    public interface IControllerActivator {
        IController Create(RequestContext requestContext, Type controllerType);
    }
}
```

Contrast this to the role of the controller factory. A controller factory is an implementation of the IControllerFactory interface, which is responsible both for locating a controller type and for instantiating an instance of that controller type.

Controller activators are responsible only for instantiating an instance of a controller type. They do not perform the controller type lookup. After locating a proper controller type, controller factories should delegate to an instance of IControllerActivator to handle the actual instantiation of the controller.

The DefaultControllerFactory class has a new constructor that accepts an IControllerFactory instance. This lets you apply Dependency Injection to manage this aspect of controller creation without having to override the default controller-type lookup behavior.

IServiceLocator Interface Replaced with IDependencyResolver

Based on community feedback, the ASP.NET MVC 3 Beta release has replaced the use of the IServiceLocator interface with a slimmed-down IDependencyResolver interface specific to the needs of ASP.NET MVC. The following example shows the new interface:

```
namespace System.Web.Mvc {
    using System.Collections.Generic;

    public interface IDependencyResolver {
        object GetService(Type serviceType);
        IEnumerable<object> GetServices(Type serviceType);
    }
}
```

As part of this change, the ServiceLocator class was also replaced with the DependencyResolver class. Registration of a dependency resolver is similar to earlier versions of ASP.NET MVC:

```
DependencyResolver.SetResolver(myResolver);
```

Implementations of this interface should simply delegate to the underlying dependency injection container to provide the registered service for the requested type.

When there are no registered services of the requested type, ASP.NET MVC expects implementations of this interface to return null from GetService and to return an empty collection from GetServices.

The new DependencyResolver class lets you register classes that implement either the new IDependencyResolver interface or the Common Service Locator interface (IServiceLocator). For more information about Common Service Locator, see CommonServiceLocator on GitHub.

New IViewActivator Interface for Fine-Grained View Page Instantiation

The new IViewPageActivator interface provides more fine-grained control over how view pages are instantiated via dependency injection. This applies to both WebFormView instances and RazorView instances. The following example shows the new interface:

```
namespace System.Web.Mvc {
    public interface IViewPageActivator {
        object Create(ControllerContext controllerContext, Type type);
    }
}
```

These classes now accept an IViewPageActivator constructor argument, which lets you use dependency injection to control how the ViewPage, ViewUserControl, and WebViewPage types are instantiated.

New Dependency Resolver Support for Existing Services

The new release includes dependency resolution support for the following services:

- Model validation providers. Classes that implement ModelValidatorProvider can be registered in the dependency resolver, and the system will use them to support client- and server-side validation.
- Model metadata provider. A single class that implements ModelMetadataProvider can be registered in the dependency resolver, and the system will use it to provide metadata for the templating and validation systems.
- Value providers. Classes that implement ValueProviderFactory can be registered in the dependency resolver, and the system will use them to create value providers that are consumed by the controller and during model binding.
- Model binders. Classes that implement IModelBinderProvider can be registered in the dependency resolver, and the system will use them to create model binders that are consumed by the model binding system.

New Support for Unobtrusive jQuery-Based Ajax

ASP.NET MVC includes Ajax helper methods such as the following:

- Ajax.ActionLink

- Ajax.RouteLink
- Ajax.BeginForm
- Ajax.BeginRouteForm

These methods use JavaScript to invoke an action method on the server rather than using a full postback. This functionality has been updated to take advantage of jQuery in an unobtrusive manner. Rather than intrusively emitting inline client scripts, these helper methods separate the behavior from the markup by emitting HTML5 attributes using the *data-ajax* prefix. Behavior is then applied to the markup by referencing the appropriate JavaScript files. Make sure that the following JavaScript files are referenced:

- jquery-1.4.1.js
- jquery.unobtrusive.ajax.js

This feature is enabled by default in the Web.config file in the ASP.NET MVC 3 new project templates, but is disabled by default for existing projects. For more information, see Added application-wide flags for client validation and unobtrusive JavaScript later in this document.

New Support for Unobtrusive jQuery Validation

By default, ASP.NET MVC 3 Beta uses jQuery validation in an unobtrusive manner in order to perform client-side validation. To enable unobtrusive client validation, make a call like the following from within a view:

```
Html.EnableClientValidation();
```

This requires that ViewContext.UnobtrusiveJavaScriptEnabled property is set to true, which you can do by making the following call:

```
Html.EnableUnobtrusiveJavaScript();
```

Also make sure the following JavaScript files are referenced.

- jquery-1.4.1.js
- jquery.validate.js
- jquery.validate.unobtrusive.js

This feature is enabled on by default in the Web.config file in the ASP.NET MVC 3 new project templates, but is disabled by default for existing projects. For more information, see New application-wide flags for client validation and unobtrusive JavaScript later in this document.

New Application-Wide Flags for Client Validation and Unobtrusive JavaScript

You can enable or disable client validation and unobtrusive JavaScript globally using static members of the HtmlHelper class, as in the following example:

```
HtmlHelper.ClientValidationEnabled = true;
HtmlHelper.UnobtrusiveJavaScriptEnabled = true;
```

The default project templates enable unobtrusive JavaScript by default. You can also enable or disable these features in the root Web.config file of your application using the following settings:

```
<configuration>
        <appSettings>
            <add key="ClientValidationEnabled" value="true"/>
            <add key="UnobtrusiveJavaScriptEnabled" value="true"/>
        </appSettings>
    </configuration>
```

Because you can enable these features by default, new overloads were introduced to the HtmlHelper class that let you override the default settings, as shown in the following examples:

```
public void EnableClientValidation();
public void EnableClientValidation(bool enabled);
public void EnableUnobtrusiveJavaScript();
public void EnableUnobtrusiveJavaScript(bool enabled);
```

For backward compatibility, both of these features are disabled by default.

New Support for Code that Runs Before Views Run

You can now put a file named _viewstart.cshtml (or _viewstart.vbhtml) in the Views directory and add code to it that will be shared among multiple views in that directory and its subdirectories. For example, you might put the following code into the _viewstart.cshtml page in the ~/Views folder:

```
@{
    Layout = "~/Views/Shared/_Layout.cshtml";
}
```

This sets the layout page for every view within the Views folder and all its subfolders recursively. When a view is being rendered, the code in the _viewstart.cshtml file runs before the view code runs. The _viewstart.cshtml code applies to every view in that folder.

By default, the code in the _viewstart.cshtml file also applies to views in any subfolder. However, individual subfolders can have their own version of the _viewstart.cshtml file; in that case, the local version takes precedence. For example, to run code that is common to all views for the HomeController, put a _viewstart.cshtml file in the ~/Views/Home folder.

New Support for the VBHTML Razor Syntax

The previous ASP.NET MVC preview included support for views using Razor syntax based on C#. These views use the .cshtml file extension. As part of ongoing work to support Razor, the ASP.NET MVC 3 Beta introduces support for the Razor syntax in Visual Basic, which uses the .vbhtml file extension.

For an introduction to using Visual Basic syntax in VBHTML pages, see the tutorial at the following URL:

https://www.asp.net/webmatrix/tutorials/asp-net-web-pages-visual-basic

More Granular Control over ValidateInputAttribute

ASP.NET MVC has always included the ValidateInputAttribute class, which invokes the core ASP.NET request validation infrastructure to make sure that the incoming request does not contain potentially malicious input. By default, input validation is enabled. It is possible to disable request validation by using the ValidateInputAttribute attribute, as in the following example:

```
[ValidateInput(false)]
public ActionResult SomeAction() {
    return View();
}
```

However, many web applications have individual form fields that need to allow HTML, while the remaining fields should not. The ValidateInputAttribute class now lets you specify a list of fields that should not be included in request validation.

For example, if you are developing a blog engine, you might want to allow markup in the Body and Summary fields. These fields might be represented by two input element, each with a name attribute corresponding to the property name ("Body" and "Summary"). To disable request validation for these fields only, specify the names (comma-separated) in the Exclude property of the ValidateInput class, as in the following example:

```
[ValidateInput(true, Exclude="Body, Summary")]
public ActionResult About() {
    return View();
}
```

Helpers Convert Underscores to Hyphens for HTML Attribute Names Specified Using Anonymous Objects

Helper methods let you specify attribute name/value pairs using an anonymous object, as in the following example:

```
Html.TextBox("Name", "Value", new {title = "Title"})
```

This approach doesn't let you use hyphens in the attribute name, because a hyphen cannot be used for a property name in ASP.NET. However, hyphens are important for custom HTML5 attributes; for example, HTML5 uses the "data-" prefix.

At the same time, underscores cannot be used for attribute names in HTML, but are valid within property names. Therefore, if you specify attributes using an anonymous object, and if the attribute names include an underscore,, helper methods will convert the underscores to hyphens. For example, the following helper syntax uses an underscore:

```
Html.TextBox("Name", "Value", new {data_required = "true"})
```

The previous example renders the following markup when the helper runs:

```
<input data-required="true" id="Name" name="Name"
       type="textbox" value="Value" />
```

Bug Fixes

The default object template for the EditorFor and DisplayFor template helpers now supports the ordering specified in the DisplayAttribute.Order property. (In previous versions, the Order setting was not used.)

Client validation now supports validation of overridden properties that have validation attributes applied.

JsonValueProviderFactory is now registered by default.

Breaking Changes

The order of execution for exception filters has changed for exception filters that have the same Order value. In ASP.NET MVC 2 and earlier, exception filters on the controller with the same Order as those on an action method were executed before the exception filters on the action method. This would typically be the case when exception filters were applied without a specified Order value. In ASP.NET MVC 3, this order has been reversed so that the most specific exception handler executes first. As in earlier versions, if the Order property is explicitly specified, the filters are run in the specified order.

Known Issues

During installation, the EULA acceptance dialog box displays the license terms in a window that is smaller than intended.

Razor views do not have IntelliSense support nor syntax highlighting. It is anticipated that support for Razor syntax in Visual Studio will be included as part of a later release.

When you are editing a Razor view (CSHTML file), the Go To Controller menu item in Visual Studio will not be available, and there are no code snippets.

When using the @model syntax to specify a strongly typed CSHTML view, language-specific shortcuts for types are not recognized. For example, @model int will not work, but @model Int32 will work. The workaround for this bug is to use the actual type name when you specify the model type.

When using the @model syntax to specify a strongly typed CSHTML view (or @ModelType to specify a strongly typed VBHTML view), nullable types and array declarations are not supported. For example, @model int? is not supported. Instead, use `@model Nullable<Int32>`. The syntax @model string[] is also not supported; instead, use `@model IList<string>`.

When you upgrade an ASP.NET MVC 2 project to ASP.NET MVC 3, make sure to add the following to the appSettings section of the Web.config file:

```
<appSettings>
  <add key="enableSimpleMembership" value="false" />
</appSettings>
```

There's a known issue that causes Forms Authentication to always redirect unauthenticated users to ~/Account/Login, ignoring the forms authentication setting used in Web.config. The workaround is to add the following app setting.

```
<add key="autoFormsAuthentication" value="false" />
```

ASP.NET MVC 4

2/20/2020 • 16 minutes to read • Edit Online

This document describes the release of ASP.NET MVC 4 Beta for Visual Studio 2010.

> **NOTE**
> This is not the most current release. The ASP.NET MVC 4 RC release notes are available here.

- Installation Notes
- Documentation
- Support
- Software Requirements
- Upgrading an ASP.NET MVC 3 Project to ASP.NET MVC 4
- New Features in ASP.NET MVC 4 Beta
  - ASP.NET Web API
  - ASP.NET Single Page Application
  - Enhancements to Default Project Templates
  - Mobile Project Template
  - Display Modes
  - jQuery Mobile, the View Switcher, and Browser Overriding
  - Recipes for Code Generation in Visual Studio
  - Task Support for Asynchronous Controllers
  - Azure SDK
  - Known Issues and Breaking Changes

Installation Notes

ASP.NET MVC 4 Beta for Visual Studio 2010 can be installed from the ASP.NET MVC 4 home page using the Web Platform Installer.

You must uninstall any previously installed previews of ASP.NET MVC 4 prior to installing ASP.NET MVC 4 Beta.

This release is not compatible with the .NET Framework 4.5 Developer Preview. You must uninstall the .NET 4.5 Developer Preview before installing the ASP.NET MVC 4 Beta.

ASP.NET MVC 4 can be installed and can run side-by-side with ASP.NET MVC 3.

Documentation

Documentation for ASP.NET MVC is available on the MSDN website at the following URL:

https://go.microsoft.com/fwlink/?LinkID=243043

Tutorials and other information about ASP.NET MVC are available on the MVC 4 page of the ASP.NET website (https://www.asp.net/mvc/mvc4).

Support

This is a preview release and is not officially supported. If you have questions about working with this release, post them to the ASP.NET MVC forum (https://forums.asp.net/1146.aspx), where members of the ASP.NET community are frequently able to provide informal support.

Software Requirements

The ASP.NET MVC 4 components for Visual Studio require PowerShell 2.0 and either Visual Studio 2010 with Service Pack 1 or Visual Web Developer Express 2010 with Service Pack 1.

Upgrading an ASP.NET MVC 3 Project to ASP.NET MVC 4

ASP.NET MVC 4 can be installed side by side with ASP.NET MVC 3 on the same computer, which gives you flexibility in choosing when to upgrade an ASP.NET MVC 3 application to ASP.NET MVC 4.

The simplest way to upgrade is to create a new ASP.NET MVC 4 project and copy all the views, controllers, code, and content files from the existing MVC 3 project to the new project and then to update the assembly references in the new project to match the old project. If you have made changes to the Web.config file in the MVC 3 project, you must also merge those changes into the Web.config file in the MVC 4 project.

To manually upgrade an existing ASP.NET MVC 3 application to version 4, do the following:

1. In all Web.config files in the project (there is one in the root of the project, one in the Views folder, and one in the Views folder for each area in your project), replace every instance of the following text:

   ```
   System.Web.Mvc, Version=3.0.0.0
   System.Web.WebPages, Version=1.0.0.0
   System.Web.Helpers, Version=1.0.0.0
   System.Web.WebPages.Razor, Version=1.0.0.0
   ```

   with the following corresponding text:

   ```
   System.Web.Mvc, Version=4.0.0.0
   System.Web.WebPages, Version=2.0.0.0
   System.Web.Helpers, Version=2.0.0.0,
    System.Web.WebPages.Razor, Version=2.0.0.0,
   ```

2. In the root Web.config file, update the *webPages:Version* element to "2.0.0.0" and add a new *PreserveLoginUrl* key that has the value "true":

   ```
   <appSettings>
     <add key="webpages:Version" value="2.0.0.0" />
     <add key="PreserveLoginUrl" value="true" />
   </appSettings>
   ```

3. In Solution Explorer, delete the reference to *System.Web.Mvc* (which points to the version 3 DLL). Then add a reference to *System.Web.Mvc* (v4.0.0.0). In particular, make the following changes to update the assembly references. Here are the details:

   a. In Solution Explorer, delete the references to the following assemblies:

      - *System.Web.Mvc*(v3.0.0.0)
      - *System.Web.WebPages*(v1.0.0.0)
      - *System.Web.Razor*(v1.0.0.0)

- *System.Web.WebPages.Deployment*(v1.0.0.0)
- *System.Web.WebPages.Razor*(v1.0.0.0)

b. Add a references to the following assemblies:

- *System.Web.Mvc*(v4.0.0.0)
- *System.Web.WebPages*(v2.0.0.0)
- *System.Web.Razor*(v2.0.0.0)
- *System.Web.WebPages.Deployment*(v2.0.0.0)
- *System.Web.WebPages.Razor*(v2.0.0.0)

4. In Solution Explorer, right-click the project name and then select Unload Project. Then right-click the name again and select Edit *ProjectName*.csproj.

5. Locate the *ProjectTypeGuids* element and replace {E53F8FEA-EAE0-44A6-8774-FFD645390401} with {E3E379DF-F4C6-4180-9B81-6769533ABE47}.

6. Save the changes, close the project (.csproj) file you were editing, right-click the project, and then select Reload Project.

7. If the project references any third-party libraries that are compiled using previous versions of ASP.NET MVC, open the root Web.config file and add the following three *bindingRedirect* elements under the *configuration* section:

```
<configuration>
  <!--... elements deleted for clarity ...-->

  <runtime>
    <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
      <dependentAssembly>
        <assemblyIdentity name="System.Web.Helpers"
             publicKeyToken="31bf3856ad364e35" />
        <bindingRedirect oldVersion="1.0.0.0" newVersion="2.0.0.0"/>
      </dependentAssembly>
      <dependentAssembly>
        <assemblyIdentity name="System.Web.Mvc"
             publicKeyToken="31bf3856ad364e35" />
        <bindingRedirect oldVersion="1.0.0.0-3.0.0.0" newVersion="4.0.0.0"/>
      </dependentAssembly>
      <dependentAssembly>
        <assemblyIdentity name="System.Web.WebPages"
             publicKeyToken="31bf3856ad364e35" />
        <bindingRedirect oldVersion="1.0.0.0" newVersion="2.0.0.0"/>
      </dependentAssembly>
    </assemblyBinding>
  </runtime>
</configuration>
```

New Features in ASP.NET MVC 4 Beta

This section describes features that have been introduced in the ASP.NET MVC 4 Beta release.

ASP.NET Web API

ASP.NET MVC 4 now includes ASP.NET Web API, a new framework for creating HTTP services that can reach a broad range of clients including browsers and mobile devices. ASP.NET Web API is also an ideal platform for building RESTful services.

ASP.NET Web API includes support for the following features:

- **Modern HTTP programming model**: Directly access and manipulate HTTP requests and responses in your

Web APIs using a new, strongly typed HTTP object model. The same programming model and HTTP pipeline is symmetrically available on the client through the new HttpClient type.

- **Full support for routes**: Web APIs now support the full set of route capabilities that have always been a part of the Web stack, including route parameters and constraints. Additionally, mapping to actions has full support for conventions, so you no longer need to apply attributes such as [HttpPost] to your classes and methods.
- **Content negotiation**: The client and server can work together to determine the right format for data being returned from an API. We provide default support for XML, JSON, and Form URL-encoded formats, and you can extend this support by adding your own formatters, or even replace the default content negotiation strategy.
- **Model binding and validation:** Model binders provide an easy way to extract data from various parts of an HTTP request and convert those message parts into .NET objects which can be used by the Web API actions.
- **Filters:** Web APIs now supports filters, including well-known filters such as the [Authorize] attribute. You can author and plug in your own filters for actions, authorization and exception handling.
- **Query composition:** By simply returning IQueryable<T>, your Web API will support querying via the OData URL conventions.
- **Improved testability of HTTP details:** Rather than setting HTTP details in static context objects, Web API actions can now work with instances of HttpRequestMessage and HttpResponseMessage. Generic versions of these objects also exist to let you work with your custom types in addition to the HTTP types.
- **Improved Inversion of Control (IoC) via DependencyResolver:** Web API now uses the service locator pattern implemented by MVC's dependency resolver to obtain instances for many different facilities.
- **Code-based configuration:** Web API configuration is accomplished solely through code, leaving your config files clean.
- **Self-host:** Web APIs can be hosted in your own process in addition to IIS while still using the full power of routes and other features of Web API.

For more details on ASP.NET Web API please visit https://www.asp.net/web-api.

ASP.NET Single Page Application

ASP.NET MVC 4 now includes an early preview of the experience for building single page applications with significant client-side interactions using JavaScript and Web APIs. This support includes:

- A set of JavaScript libraries for richer local interactions with cached data
- Additional Web API components for unit of work and DAL support
- An MVC project template with scaffolding to get started quickly

For more details on the Single Page Application support in ASP.NET MVC 4 please visit https://www.asp.net/single-page-application.

Enhancements to Default Project Templates

The template that is used to create new ASP.NET MVC 4 projects has been updated to create a more modern-looking website:

In addition to cosmetic improvements, there's improved functionality in the new template. The template employs a technique called adaptive rendering to look good in both desktop browsers and mobile browsers without any customization.

To see adaptive rendering in action, you can use a mobile emulator or just try resizing the desktop browser

window to be smaller. When the browser window gets small enough, the layout of the page will change.

Another enhancement to the default project template is the use of JavaScript to provide a richer UI. The Login and Register links that are used in the template are examples of how to use the jQuery UI Dialog to present a rich login screen:

Mobile Project Template

If you're starting a new project and want to create a site specifically for mobile and tablet browsers, you can use the new Mobile Application project template. This is based on jQuery Mobile, an open-source library for building touch-optimized UI:

This template contains the same application structure as the Internet Application template (and the controller code is virtually identical), but it's styled using jQuery Mobile to look good and behave well on touch-based mobile devices. To learn more about how to structure and style mobile UI, see the jQuery Mobile project website.

If you already have a desktop-oriented site that you want to add mobile-optimized views to, or if you want to create a single site that serves differently styled views to desktop and mobile browsers, you can use the new Display Modes feature. (See the next section.)

Display Modes

The new Display Modes feature lets an application select views depending on the browser that's making the request. For example, if a desktop browser requests the Home page, the application might use the Views\Home\Index.cshtml template. If a mobile browser requests the Home page, the application might return the Views\Home\Index.mobile.cshtml template.

Layouts and partials can also be overridden for particular browser types. For example:

- If your Views\Shared folder contains both the _Layout.cshtml and _Layout.mobile.cshtml templates, by default the application will use _Layout.mobile.cshtml during requests from mobile browsers and _Layout.cshtml during other requests.
- If a folder contains both _MyPartial.cshtml and _MyPartial.mobile.cshtml, the instruction @Html.Partial("_MyPartial") will render _MyPartial.mobile.cshtml during requests from mobile browsers, and _MyPartial.cshtml during other requests.

If you want to create more specific views, layouts, or partial views for other devices, you can register a new *DefaultDisplayMode* instance to specify which name to search for when a request satisfies particular conditions. For example, you could add the following code to the *Application_Start* method in the Global.asax file to register the string "iPhone" as a display mode that applies when the Apple iPhone browser makes a request:

```
DisplayModeProvider.Instance.Modes.Insert(0, new
DefaultDisplayMode("iPhone")
{
    ContextCondition = (context => context.GetOverriddenUserAgent().IndexOf
        ("iPhone", StringComparison.OrdinalIgnoreCase) >= 0)
 });
```

After this code runs, when an Apple iPhone browser makes a request, your application will use the Views\Shared_Layout.iPhone.cshtml layout (if it exists).

jQuery Mobile, the View Switcher, and Browser Overriding

jQuery Mobile is an open source library for building touch-optimized web UI. If you want to use jQuery Mobile with an ASP.NET MVC 4 application, you can download and install a NuGet package that helps you get started. To install it from the Visual Studio Package Manager Console, type the following command:

```
Install-Package jQuery.Mobile.MVC
```

This installs jQuery Mobile and some helper files, including the following:

- Views/Shared/_Layout.Mobile.cshtml, which is a jQuery Mobile-based layout.
- A view-switcher component, which consists of the Views/Shared/_ViewSwitcher.cshtml partial view and the ViewSwitcherController.cs controller.

After you install the package, run your application using a mobile browser (or equivalent, like the Firefox User Agent Switcher add-on). You'll see that your pages look quite different, because jQuery Mobile handles layout and styling. To take advantage of this, you can do the following:

- Create mobile-specific view overrides as described under Display Modes earlier (for example, create Views\Home\Index.mobile.cshtml to override Views\Home\Index.cshtml for mobile browsers).
- Read the jQuery Mobile documentation to learn more about how to add touch-optimized UI elements in mobile views.

A convention for mobile-optimized web pages is to add a link whose text is something like Desktop view or Full site mode that lets users switch to a desktop version of the page. The jQuery.Mobile.MVC package includes a sample view-switcher component for this purpose. It's used in the default Views\Shared_Layout.Mobile.cshtml

view, and it looks like this when the page is rendered:

If visitors click the link, they're switched to the desktop version of the same page.

Because your desktop layout will not include a view switcher by default, visitors won't have a way to get to mobile mode. To enable this, add the following reference to _*ViewSwitcher* to your desktop layout, just inside the *<body>* element:

```
<body>
    @Html.Partial("_ViewSwitcher")
    ...
```

The view switcher uses a new feature called Browser Overriding. This feature lets your application treat requests as if they were coming from a different browser (user agent) than the one they're actually from. The following table lists the methods that Browser Overriding provides.

`HTTPCONTEXT.SETOVERRIDDENBROWSER(USERAGENTSTRING)`	**OVERRIDES THE REQUEST'S ACTUAL USER AGENT VALUE USING THE SPECIFIED USER AGENT.**
`HttpContext.GetOverriddenUserAgent()`	Returns the request's user agent override value, or the actual user agent string if no override has been specified.
`HttpContext.GetOverriddenBrowser()`	Returns an *HttpBrowserCapabilitiesBase* instance that corresponds to the user agent currently set for the request (actual or overridden). You can use this value to get properties such as *IsMobileDevice*.
`HttpContext.ClearOverriddenBrowser()`	Removes any overridden user agent for the current request.

Browser Overriding is a core feature of ASP.NET MVC 4 and is available even if you don't install the jQuery.Mobile.MVC package. However, it affects only view, layout, and partial-view selection — it does not affect any other ASP.NET feature that depends on the *Request.Browser* object.

By default, the user-agent override is stored using a cookie. If you want to store the override elsewhere (for example, in a database), you can replace the default provider (*BrowserOverrideStores.Current*). Documentation for this provider will be available to accompany a later release of ASP.NET MVC.

Recipes for Code Generation in Visual Studio

The new Recipes feature enables Visual Studio to generate solution-specific code based on packages that you can install using NuGet. The Recipes framework makes it easy for developers to write code-generation plugins, which you can also use to replace the built-in code generators for Add Area, Add Controller, and Add View. Because recipes are deployed as NuGet packages, they can easily be checked into source control and shared with all developers on the project automatically. They are also available on a per-solution basis.

Task Support for Asynchronous Controllers

You can now write asynchronous action methods as single methods that return an object of type *Task* or *Task<ActionResult>*.

For example, if you're using Visual C# 5 (or using the Async CTP), you can create an asynchronous action method that looks like the following:

```
public async Task<ActionResult> Index(string city) {
    var newsService = new NewsService();
    var sportsService = new SportsService();

    return View("Common",
        new PortalViewModel {
        NewsHeadlines = await newsService.GetHeadlinesAsync(),
        SportsScores = await sportsService.GetScoresAsync()
    });
}
```

In the previous action method, the calls to *newsService.GetHeadlinesAsync* and *sportsService.GetScoresAsync* are called asynchronously and do not block a thread from the thread pool.

Asynchronous action methods that return *Task* instances can also support timeouts. To make your action method cancellable, add a parameter of type *CancellationToken* to the action method signature. The following example shows an asynchronous action method that has a timeout of 2500 milliseconds and that displays a *TimedOut* view to the client if a timeout occurs.

```
[AsyncTimeout(2500)]
[HandleError(ExceptionType = typeof(TaskCanceledException), View = "TimedOut")]
public async Task<ActionResult> Index(string city,
    CancellationToken cancellationToken) {
    var newsService = new NewsService();
    var sportsService = new SportsService();

    return View("Common",
        new PortalViewModel {
        NewsHeadlines = await newsService.GetHeadlinesAsync(cancellationToken),
        SportsScores = await sportsService.GetScoresAsync(cancellationToken)
    });
}
```

Azure SDK

ASP.NET MVC 4 Beta supports the September 2011 1.5 release of the Windows Azure SDK.

Known Issues and Breaking Changes

- **After installing ASP.NET MVC 4 Beta, the CSHTML/VBHTML editor in Visual Studio 2010 Service Pack 1 CSHTML/VBHTML editor may pause for a long time after typing snippet or JavaScript inside cshtml or vbhtml files.** This occurs only in ASP.NET MVC 4 applications which have just been created and have not yet been compiled.

  The workaround is to compile the project to get the assemblies in the bin folder. Note, if you clean the project which removes the assemblies from the bin folder, the editor problem will come back.

  This will be corrected in the next release.

- **C# Project templates for Visual Studio 11 Beta contain an incorrect connection string in Global.asax.cs.** The default connection specified in the Application_Start method for projects created in Visual Studio 11 Beta contain a LocalDB connection string which contains an unescaped backslash () character. This results in a connection error upon attempts to access a Entity Framework DbContext, which generates a SqlException.

  To correct this issue, escape the backslash character in the App_Start method of Global.asax.cs so that it reads as follows:

```
Database.DefaultConnectionFactory =
   new SqlConnectionFactory(
     "Data Source=(localdb)\\v11.0; Integrated Security=True; MultipleActiveResultSets=True");
```

- **ASP.NET MVC 4 applications which target .NET 4.5 will throw a FileLoadException upon attempt to access the System.Net.Http.dll assembly when run under .NET 4.0.** ASP.NET MVC 4 applications created under .NET 4.5 contain a binding redirect that will result in a FileLoadException which that states "Could not load file or assembly 'System.Net.Http' or one of its dependencies." when the application is executed on a system with .NET 4.0 installed. To correct this issue, remove the following binding redirect from web.config:

```
<dependentAssembly>
 <assemblyIdentity name="System.Net.Http" publicKeyToken="b03f5f7f11d50a3a"
    culture="neutral" />
 <bindingRedirect oldVersion="0.0.0.0-4.0.0.0" newVersion="4.0.0.0" />
</dependentAssembly>
```

  The assembly binding element in the modified web.config should appear as follows:

```
<assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
 <dependentAssembly>
  <assemblyIdentity name="System.Web.Helpers"
    publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-2.0.0.0" newVersion="2.0.0.0" />
 </dependentAssembly>
 <dependentAssembly>
  <assemblyIdentity name="System.Web.Mvc"
    publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-4.0.0.0" newVersion="4.0.0.0" />
 </dependentAssembly>
 <dependentAssembly>
  <assemblyIdentity name="System.Web.WebPages"
    publicKeyToken="31bf3856ad364e35" />
  <bindingRedirect oldVersion="1.0.0.0-2.0.0.0" newVersion="2.0.0.0" />
 </dependentAssembly>
</assemblyBinding>
```

- **The "Add Controller" item template in Visual Basic projects generates an incorrect namespace when invokedfrom inside an area.** When you add a controller to an area in an ASP.NET MVC project that uses Visual Basic, the item template inserts the wrong namespace into the controller. The result is a "file not found" error when you navigate to any action in the controller.

  The generated namespace omits everything after the root namespace. For example, the namespace generated is *RootNamespace* but should be *RootNamespace.Areas.AreaName.Controllers* .

- **Breaking changes in the Razor View Engine.** As part of a rewrite of the Razor parser, the following types were removed from *System.Web.Mvc.Razor*:

  - *ModelSpan*
  - *MvcVBRazorCodeGenerator*
  - *MvcCSharpRazorCodeGenerator*
  - *MvcVBRazorCodeParser*

  The following methods were also removed:

  - *MvcCSharpRazorCodeParser.ParseInheritsStatement(System.Web.Razor.Parser.CodeBlockInfo)*
  - *MvcWebPageRazorHost.DecorateCodeGenerator(System.Web.Razor.Generator.RazorCodeGenerator)*
  - *MvcVBRazorCodeParser.ParseInheritsStatement(System.Web.Razor.Parser.CodeBlockInfo)*

- **When WebMatrix.WebData.dll is included in the /bin directory of an ASP.NET MVC 4 apps, it takes over the URL for forms authentication.** Adding the WebMatrix.WebData.dll assembly to your application (for example, by selecting "ASP.NET Web Pages with Razor Syntax" when using the Add Deployable Dependencies dialog) will override the authentication login redirect to /account/logon rather than /account/login as expected by the default ASP.NET MVC Account Controller. To prevent this behavior and use the URL specified already in the authentication section of web.config, you can add an appSetting called PreserveLoginUrl and set it to true:

```
<appSettings>
    <add key="PreserveLoginUrl" value="true"/>
</appSettings>
```

- **The NuGet package manager fails to install when attempting to install ASP.NET MVC 4 for side by side installations of Visual Studio 2010 and Visual Web Developer 2010.** To run Visual Studio 2010 and Visual Web Developer 2010 side by side with ASP.NET MVC 4 you must install ASP.NET MVC 4 after both versions of Visual Studio have already been installed.

- **Uninstalling ASP.NET MVC 4 fails if prerequisites have already been uninstalled.** To cleanly uninstall ASP.NET MVC 4you must uninstall ASP.NET MVC 4 prior to uninstalling Visual Studio.

- **Running a default Web API project shows instructions that incorrectly direct the user to add routes using the RegisterApis method, which doesn't exist.** Routes should be added in the RegisterRoutes method using the ASP.NET route table.

- **Installing ASP.NET MVC 4 Beta breaks ASP.NET MVC 3 RTM applications.** ASP.NET MVC 3 applications that were created with the RTM release (not with the ASP.NET MVC 3 Tools Update release) require the following changes in order to work side-by-side with ASP.NET MVC 4 Beta. Building the project without making these updates results in compilation errors.

  Required updates

  1. In the root Web.config file, add a new *<appSettings>* entry with the key *webPages:Version* and the value *1.0.0.0*.

     ```
     <appSettings>
         <add key="webpages:Version" value="1.0.0.0"/>
         <add key="ClientValidationEnabled" value="true"/>
         <add key="UnobtrusiveJavaScriptEnabled" value="true"/>
     </appSettings>
     ```

  2. In Solution Explorer, right-click the project name and then select Unload Project. Then right-click the name again and select Edit *ProjectName*.csproj.

  3. Locate the following assembly references:

     ```
     <Reference Include="System.Web.WebPages"/>
     <Reference Include="System.Web.Helpers" />
     ```

     Replace them with the following:

     ```
     <Reference Include="System.Web.WebPages, Version=1.0.0.0,
     Culture=neutral, PublicKeyToken=31bf3856ad364e35, processorArchitecture=MSIL "/>
     <Reference Include="System.Web.Helpers, Version=1.0.0.0,
     Culture=neutral, PublicKeyToken=31bf3856ad364e35, processorArchitecture=MSIL" />
     ```

4. Save the changes, close the project (.csproj) file you were editing, and then right-click the project and select Reload.

Running ASP.NET 1.1 with IIS 6.0

2/20/2020 • 7 minutes to read • Edit Online

While Windows Server 2003 includes both IIS 6.0 and ASP.NET 1.1, these components are disabled by default. This whitepaper describes how to enable IIS 6.0 and ASP.NET 1.1, and recommends several configuration settings to get the optimal performance from IIS and ASP.NET.

Applies to ASP.NET 1.1 and IIS 6.0.

ASP.NET 1.1 ships with Windows Server 2003, which also includes the latest version of Internet Information Server (IIS) version 6.0. IIS 6.0 and ASP.NET 1.1 are designed to integrate seamlessly and ASP.NET now defaults to the new IIS 6.0 worker process model.

ASP.NET 1.1 is not installed by default

Unlike previous versions of Microsoft's server operating systems, Internet Information Server (IIS) is not enabled by default; nor is ASP.NET 1.1. There are two options for enabling IIS:

Enabling IIS, option #1 - Configure Your Server Wizard

Windows Server 2003 ships a new 'Configure Your Server Wizard' to help you properly configure your server in the desired mode.

To start the wizard - note, to run the wizard you must be logged in as an administrator - go to: Start | Programs | Administrative Tools and select 'Configure Your Server'.

Once selected you should see the 'Configure Your Server Wizard' opening screen:

Click 'Next >':

Click 'Next >'

On this screen you will need to select 'Application server (IIS, ASP.NET) as the options to configure.

Click 'Next >'.

After selecting to configure the server as an Application Server, this screen will be displayed prompting what additional capabilities should be installed. Neither option is selected by default. To enable ASP.NET automatically, you need to select 'Enable ASP.NET'.

Click 'Next >'.

This screen displays what options are to be installed.

Click 'Next >'.

You will see this screen while the options you selected are being installed. It is normal to see other dialog boxes appear as services are being installed. You may additionally be prompted for the location of the Windows 2003 Server installation CD.

Click 'Next >' when complete.

Click 'Finish' - the Windows Server 2003 is now configured to support IIS 6.0 and ASP.NET 1.1.

Enabling IIS, option #2 - Manually configuring IIS and ASP.NET

If you do not wish to use the 'Configure Your Server Wizard' you can optionally install IIS 6.0 and ASP.NET 1.1 using 'Add or Remove Programs' from the Control Panel.

First open the Control Panel:

Next, click on 'Add/Remove Windows Components' which will open the 'Windows Components Wizard':

Highlight and check 'Application Server' and then click the 'Details?' button:

To install ASP.NET, check 'ASP.NET'.

Click 'OK' to return to the Windows Component Wizard. Click 'Next >' from the Windows Component Wizard to begin installing:

It is normal to see other dialog boxes appear as services are being installed. You may additionally be prompted for the location of the Windows 2003 Server installation CD.

When installation is complete you will see the last screen of the Windows Component Wizard:

IIS 6.0 and ASP.NET 1.1 are now configured and available.

Recommended Settings

When running ASP.NET 1.1 with IIS 6.0 there are several configuration settings that are recommended to get the optimal performance from ASP.NET:

- Configuring worker process memory limits
- Configuring worker process recycling

Configuring worker process memory limits

By default IIS 6.0 does not set a limit on the amount of memory that IIS is allowed to use. ASP.NET's Cache feature relies on a limitation of memory so the Cache can proactively remove unused items from memory.

It is recommended that you configure the memory recycling feature of IIS 6.0. To configure this open Internet Information Services Manager (Start | Programs | Administrative Tools | Internet Information Services). Once open, expand the 'Application Pools' folder:

For each application pool:

1. Right-click on the application pool, e.g. 'DefaultAppPool', and select 'Properties':

2. Next, enable Memory recycling by clicking on either 'Maximum used memory (in megabytes):'. The value should not be more than the amount of physical (not virtual) memory on the server, a good approximation is 60% of the physical memory, i.e. for a server with 512MB of physical memory select 310. It is also recommended that the maximum not exceed 800MB when using a 2GB address space. If the memory address space of the server is 3GB, the maximum memory limit for the worker process can be as high as 1,800MB:

Click 'Apply' and the 'OK' to exit the properties dialog. Repeat this for all available application pools.

Configuring worker recycling

By default IIS 6.0 is configured to recycle its worker process every 29 hours. This is a bit aggressive for an application running ASP.NET and it is recommended that automatic worker process recycling is disabled.

To disable automatic worker process recycling, first open Internet Information Services Manager (Start | Programs | Administrative Tools | Internet Information Services). Once open, expand the 'Application Pools' folder:

For each application pool:

1. Right-click on the application pool, e.g. 'DefaultAppPool', and select 'Properties':

2. Uncheck 'Recycle worker process (in minutes):':

Click 'Apply' and the 'OK' to exit the properties dialog. Repeat this for all available application pools.

Granting write access to the file system

If your application requires write access to the file system and you are using NTFS you will need to modify an Access Control List (ACL) on the folder or file to grant ASP.NET access to.

For example, to grant ASP.NET write access to the c:\inetpub\wwwroot first open explorer and navigate to the directory:

Next, right-click on the directory, e.g. 'wwwroot' and select properties. After the properties dialog opens, select the 'Security' tab:

The c:\inetpub\wwwroot\ directory is a special directory in that the special IIS 6.0 group 'IIS_WPG' is already granted Read & Execute, List Folder Contents, and Read permissions. However, to grant Write permission, you need to click the Allow checkbox for Write:

IIS 6.0 now has write permission on this folder. To grant write permissions on other folders, follow these steps - note, you may need to add the IIS_WPG group if it does not already exist.

Caution

Granting write permission to IIS_WPG will allow any ASP.NET application to write to this directory.

Supporting integrated authentication with SQL Server

Integrated authentication allows for SQL Server to leverage Windows NT authentication to validate SQL Server logon accounts. This allows the user to bypass the standard SQL Server logon process. With this approach, a network user can access a SQL Server database without supplying a separate logon identification or password because SQL Server obtains the user and password information from the Windows NT network security process.

Choosing integrated authentication for ASP.NET applications is a good choice because no credentials are ever stored within your connection string for your application. Rather the connection string used to connect to SQL will look as follows:

```
"server=localhost; database=Northwind;Trusted_Connection=true"
```

This connection string tells SQL Server to use the Windows credentials of the application attempting to access SQL Server. In the case of ASP.NET/IIS 6 this would be an account in the IIS_WPG group.

To enable integrated authentication between SQL Server and ASP.NET, you will need to first ensure that SQL Server is configured for either Integrated authentication or Mixed-Mode authentication - check with your DBA to determine this. If SQL Server is in one of these two modes, you can use integrated authentication.

Open SQL Server Enterprise Manager (Start | Programs | Microsoft SQL Server | Enterprise Manager), select the appropriate server, and expand the Security folder:

If 'BUILTINT\IIS_WPG' group is not listed, right-click on Logins and select 'New Login':

In the 'Name:' textbox either enter '[Server/Domain Name]\IIS_WPG' or click on the ellipses button to open the Windows NT user/group picker:

Select the current machine's IIS_WPG group and click 'Add' and OK to close the picker.

You then need to also set the default database and the permissions to access the database. To set the default database choose from the drop down list, e.g. below Northwind is selected:

Next, click on the Database Access tab:

Click on the Permit checkbox for every database that you wish to allow access to. You will also need to select database roles, checking db_owner will ensure your login has all necessary permissions to manage and use the selected database.

Click OK to exit the property dialog. Your ASP.NET application is now configured to support integrated SQL Server authentication.

Don't run ASP.NET 1.0 in IIS 6.0 native mode

ASP.NET 1.0 on IIS 6.0 is only supported in IIS 5 compatibility mode.

To configure ASP.NET 1.0 to run in IIS 5.0 compatibility mode, open Internet Services Manager and right click Web Sites and select properties:

Switch to the Service Tab and check ?Run WWW Service in IIS 5.0 Isolation Mode?:

How To: Add Mobile Pages to Your ASP.NET Web Forms / MVC Application

2/20/2020 • 26 minutes to read • Edit Online

Applies To

- ASP.NET Web Forms version 4.0
- ASP.NET MVC version 3.0

Summary

This How To describes various ways to serve pages optimized for mobile devices from your ASP.NET Web Forms / MVC application, and suggests architectural and design issues to consider when targeting a broad range of devices. This document also explains why the ASP.NET Mobile Controls from ASP.NET 2.0 to 3.5 are now obsolete, and discusses some modern alternatives.

Contents

- Overview
- Architectural options
- Browser and device detection
- How ASP.NET Web Forms applications can present mobile-specific pages
- How ASP.NET MVC applications can present mobile-specific pages
- Additional resources

For downloadable code samples demonstrating this white paper's techniques for both ASP.NET Web Forms and MVC, see Mobile Apps & Sites with ASP.NET.

Overview

Mobile devices – smartphones, feature phones, and tablets – continue to grow in popularity as a means to access the Web. For many web developers and web-oriented businesses, this means it's increasingly important to provide a great browsing experience for visitors using those devices.

How earlier versions of ASP.NET supported mobile browsers

ASP.NET versions 2.0 to 3.5 included *ASP.NET Mobile Controls*: a set of server controls for mobile devices in the *System.Web.Mobile.dll* assembly and the *System.Web.UI.MobileControls* namespace. The assembly is still included in ASP.NET 4, but it is deprecated. Developers are advised to migrate to more modern approaches, such as those described in this paper.

The reason why ASP.NET Mobile Controls have been marked as obsolete is that their design is oriented around the mobile phones that were common around 2005 and earlier. The controls are mainly designed to render WML or cHTML markup (instead of regular HTML) for the WAP browsers of that era. But WAP, WML, and cHTML are no longer relevant for most projects, because HTML has now become the ubiquitous markup language for mobile and desktop browsers alike.

The challenges of supporting mobile devices today

Even though mobile browsers now almost universally support HTML, you will still face many challenges when aiming to create great mobile browsing experiences:

- *Screen size* - Mobile devices vary dramatically in form, and their screens are often much smaller than desktop monitors. So, you may need to design completely different page layouts for them.
- *Input methods* – Some devices have keypads, some have styluses, others use touch. You may need to consider multiple navigation mechanisms and data input methods.
- *Standards compliance* – Many mobile browsers do not support the latest HTML, CSS, or JavaScript standards.
- *Bandwidth* – Cellular data network performance varies wildly, and some end users are on tariffs that charge by the megabyte.

There's no one-size-fits-all solution; your application will have to look and behave differently according to the device accessing it. Depending on what level of mobile support you want, this can be a bigger challenge for web developers than the desktop "browser wars" ever was.

Developers approaching mobile browser support for the first time often initially think it's only important to support the latest and most sophisticated smartphones (e.g., Windows Phone 7, iPhone, or Android), perhaps because developers often personally own such devices. However, cheaper phones are still extremely popular, and their owners do use them to browse the web – especially in countries where mobile phones are easier to get than a broadband connection. Your business will need to decide what range of devices to support by considering its likely customers. If you're building an online brochure for a luxury health spa, you might make a business decision only to target advanced smartphones, whereas if you're creating a ticket booking system for a cinema, you probably need to account for visitors with less powerful feature phones.

Architectural options

Before we get to the specific technical details of ASP.NET Web Forms or MVC, note that web developers in general have three main possible options for supporting mobile browsers:

1. *Do nothing* – You can simply create a standard, desktop-oriented web application, and rely on mobile browsers to render it acceptably.

   - **Advantage**: It's the cheapest option to implement and maintain – no extra work

   - **Disadvantage**: Gives the worst end-user experience:

     - The latest smartphones may render your HTML just as well as a desktop browser, but users will still be forced to zoom and scroll horizontally and vertically to consume your content on a small screen. This is far from optimal.
     - Older devices and feature phones may fail to render your markup in a satisfactory way.
     - Even on the latest tablet devices (whose screens can be as big as laptop screens), different interaction rules apply. Touch-based input works best with larger buttons and links spread further apart, and there's no way to hover a mouse cursor over a fly-out menu.
2. *Solve the problem on the client* – With careful use of CSS and progressive enhancement you can create markup, styles, and scripts that adapt to whatever browser is running them. For example, with CSS 3 media queries, you could create a multi-column layout that turns into a single column layout on devices whose screens are narrower than a chosen threshold.

   - **Advantage**: Optimizes rendering for the specific device in use, even for unknown future devices according to whatever screen and input characteristics they have
   - **Advantage**: Easily lets you share server-side logic across all device types – minimal duplication of code or effort
   - **Disadvantage**: Mobile devices are so different from desktop devices that you may really want your mobile pages to be completely different from your desktop pages, showing different information. Such variations can be inefficient or impossible to achieve robustly through CSS alone, especially considering how inconsistently older devices interpret CSS rules. This is particularly true of CSS 3 attributes.

- **Disadvantage**: Provides no support for varying server-side logic and workflows for different devices. You can't, for example, implement a simplified shopping cart checkout workflow for mobile users by means of CSS alone.
- **Disadvantage**: Inefficient bandwidth use. You server may have to transmit the markup and styles that apply to all possible devices, even though the target device will only use a subset of that information.

3. ***Solve the problem on the server*** – If your server knows what device is accessing it – or at least the characteristics of that device, such as its screen size and input method, and whether it's a mobile device – it can run different logic and output different HTML markup.

- **Advantage:** Maximum flexibility. There's no limit to how much you can vary your server-side logic for mobiles or optimize your markup for the desired, device-specific layout.
- **Advantage:** Efficient bandwidth use. You only need to transmit the markup and styling information that the target device is going to use.
- **Disadvantage:** Sometimes forces repetition of effort or code (e.g., making you create similar but slightly different copies of your Web Forms pages or MVC views). Where possible you will factor out common logic into an underlying layer or service, but still, some parts of your UI code or markup may have to be duplicated and then maintained in parallel.
- **Disadvantage:** Device detection is not trivial. It requires a list or database of known device types and their characteristics (which may not always be perfectly up-to-date) and isn't guaranteed to accurately match every incoming request. This document describes some options and their pitfalls later.

To get the best results, most developers find they need to combine options (2) and (3). Minor stylistic differences are best accommodated on the client using CSS or even JavaScript, whereas major differences in data, workflow, or markup are most effectively implemented in server-side code.

This paper focuses on server-side techniques

Since ASP.NET Web Forms and MVC are both primarily server-side technologies, this white paper will focus on server-side techniques that let you produce different markup and logic for mobile browsers. Of course, you can also combine this with any client-side technique (e.g., CSS 3 media queries, progressive-enhancement JavaScript), but that's more a matter of web design than ASP.NET development.

Browser and device detection

The key prerequisite for all server-side techniques for supporting mobile devices is to know what device your visitor is using. In fact, even better than knowing the manufacturer and model number of that device is knowing the *characteristics* of the device. Characteristics may include:

- Is it a mobile device?
- Input method (mouse/keyboard, touch, keypad, joystick, ...)
- Screen size (physically and in pixels)
- Supported media and data formats
- Etc.

It's better to make decisions based on characteristics than model number, because then you'll be better equipped to handle future devices.

Using ASP.NET's built-in browser detection support

ASP.NET Web Forms and MVC developers can immediately discover important characteristics of a visiting browser by inspecting properties of the *Request.Browser* object. For example, see

- Request.Browser.IsMobileDevice
- Request.Browser.MobileDeviceManufacturer, Request.Browser.MobileDeviceModel
- Request.Browser.ScreenPixelsWidth

- Request.Browser.SupportsXmlHttp
- ...and many others

Behind the scenes, the ASP.NET platform matches the incoming *User-Agent* (UA) HTTP header against regular expressions in a set of Browser Definition XML files. By default the platform includes definitions for many common mobile devices, and you can add custom Browser Definition files for others you wish to recognize. For more details, see the MSDN page ASP.NET Web Server Controls and Browser Capabilities.

Using the WURFL device database via 51Degrees.mobi Foundation

While ASP.NET's built-in browser detection support will be sufficient for many applications, there are two main cases when it might not be enough:

- ***You want to recognize the latest devices***(without manually creating Browser Definition files for them). Note that .NET 4's Browser Definition files are not recent enough to recognize Windows Phone 7, Android phones, Opera Mobile browsers, or Apple iPads.
- ***You need more detailed information about device capabilities***. You may need to know about a device's input method (e.g., touch vs keypad), or what audio formats the browser supports. This information isn't available in the standard Browser Definition files.

The *Wireless Universal Resource File* (WURFL) project maintains much more up-to-date and detailed information about mobile devices in use today.

The great news for .NET developers is that ASP.NET's browser detection feature is extensible, so it's possible to enhance it to overcome these problems. For example, you can add the open source *51Degrees.mobi Foundation* library to your project. It's an ASP.NET IHttpModule or Browser Capabilities Provider (usable on both Web Forms and MVC applications), that directly reads WURFL data and hooks it into ASP.NET's built-in browser detection mechanism. Once you've installed the module, *Request.Browser* will suddenly contain a lot more accurate and detailed information: it will correctly recognize many of the devices previously mentioned and list their capabilities (including additional capabilities such as input method). See the project's documentation for more details.

How Web Forms applications can present mobile-specific pages

By default, here's how a brand new Web Forms application displays on common mobile devices:

Windows Phone 7

Opera Mobile
(using same resolution as HTC Hero)

Clearly, neither layout looks very mobile-friendly – this page was designed for a large, landscape-oriented monitor, not for a small portrait-oriented screen. So what can you do about it?

As discussed earlier in this paper, there are many ways to tailor your pages for mobile devices. Some techniques

are server-based, others run on the client.

Creating a mobile-specific master page

Depending on your requirements, you may be able to use the same Web Forms for all visitors, but have two separate master pages: one for desktop visitors, another for mobile visitors. This gives you the flexibility of changing the CSS stylesheet or your top-level HTML markup to suit mobile devices, without forcing you to duplicate any page logic.

This is easy to do. For example, you can add a PreInit handler such as the following to a Web Form:

```
protected void Page_PreInit(object sender, EventArgs e)
{
    if (Request.Browser.IsMobileDevice)
        MasterPageFile = "~/Mobile.Master";
}
```

Now, create a master page called Mobile.Master in the top-level folder of your application, and it will be used when a mobile device is detected. Your mobile master page can reference a mobile-specific CSS stylesheet if necessary. Desktop visitors will still see your default master page, not the mobile one.

Creating independent mobile-specific Web Forms

For maximum flexibility, you can go much further than just having separate master pages for different device types. You can implement two *totally separate sets of Web Forms pages* – one set for desktop browsers, another set for mobiles. This works best if you want to present very different information or workflows to mobile visitors. The rest of this section describes this approach in detail.

Assuming you already have a Web Forms application designed for desktop browsers, the easiest way to proceed is to create a subfolder called "Mobile" within your project, and build your mobile pages there. You can construct an entire sub-site, with its own master pages, style sheets, and pages, using all the same techniques that you'd use for any other Web Forms application. You don't necessarily need to produce a mobile equivalent for *every* page in your desktop site; you can choose what subset of functionality makes sense for mobile visitors.

Your mobile pages can share common static resources (such as images, JavaScript, or CSS files) with your regular pages if you wish. Since your "Mobile" folder will *not* be marked as a separate application when hosted in IIS (it's just a simple subfolder of Web Forms pages), it will also share all the same configuration, Session data, and other infrastructure as your desktop pages.

> **NOTE**
>
> Since this approach usually involves some duplication of code (mobile pages are likely to share some similarities with desktop pages), it's important to factor out any common business logic or data access code into a shared underlying layer or service. Otherwise, you'll double the effort of creating and maintaining your application.

Redirecting mobile visitors to your mobile pages

It's often convenient to redirect mobile visitors to the mobile pages only on the *first* request in their browsing session (and not on every request in their session), because:

- You can then easily allow mobile visitors to access your desktop pages if they wish – just put a link on your master page that goes to "Desktop version". The visitor won't be redirected back to a mobile page, because it's no longer the first request in their session.
- It avoids the risk of interfering with requests for any dynamic resources shared between desktop and mobile parts of your site (e.g., if you have a common Web Form that both desktop and mobile parts of your site display in an IFRAME, or certain Ajax handlers)

To do this, you can place your redirection logic in a `Session_Start` method. For example, add the following

method to your Global.asax.cs file:

```
void Session_Start(object sender, EventArgs e)
{
    // Redirect mobile users to the mobile home page
    HttpRequest httpRequest = HttpContext.Current.Request;
    if (httpRequest.Browser.IsMobileDevice)
    {
        string path = httpRequest.Url.PathAndQuery;
        bool isOnMobilePage = path.StartsWith("/Mobile/",
                                StringComparison.OrdinalIgnoreCase);
        if (!isOnMobilePage)
        {
            string redirectTo = "~/Mobile/";

            // Could also add special logic to redirect from certain
            // recognized pages to the mobile equivalents of those
            // pages (where they exist). For example,
            // if (HttpContext.Current.Handler is UserRegistration)
            //     redirectTo = "~/Mobile/Register.aspx";

            HttpContext.Current.Response.Redirect(redirectTo);
        }
    }
}
```

Configuring Forms Authentication to respect your mobile pages

Note that Forms Authentication makes certain assumptions about where it can redirect visitors during and after the authentication process:

- When a user needs to be authenticated, Forms Authentication will redirect them to your desktop login page, regardless of whether they're a desktop or mobile user (because it only has a concept of *one* login URL). Assuming you want to style your mobile login page differently, you need to enhance your desktop login page so that it redirects mobile users to a separate mobile login page. For example, add the following code to your **desktop** login page code-behind:

  ```
  public partial class Login : System.Web.UI.Page
  {
      protected void Page_Load(object sender, EventArgs e)
      {
          // Ensure that if Forms Authentication forces a mobile user
          // to log in, we display the mobile login page
          string returnUrl = Request.QueryString["ReturnUrl"];
          if (!String.IsNullOrEmpty(returnUrl) && returnUrl.StartsWith("/Mobile/",
                                                StringComparison.OrdinalIgnoreCase))
          {
              Response.Redirect("~/Mobile/Account/Login.aspx?ReturnUrl="
                                + HttpUtility.UrlEncode(returnUrl));
          }

          RegisterHyperLink.NavigateUrl = "Register.aspx?ReturnUrl="
                                        + HttpUtility.UrlEncode(returnUrl);
      }
  }
  ```

- After a user successfully logs in, Forms Authentication will by default redirect them to your desktop home page (because it only has a concept of *one* default page). You need to enhance your mobile login page so that it redirects to the mobile home page after a successful log-in. For example, add the following code to your **mobile** login page code-behind:

```
public partial class Login : System.Web.UI.Page
{
    protected void Page_Load(object sender, EventArgs e)
    {
        // Ensure that after logging in, mobile users stay on mobile pages
        string returnUrl = Request.QueryString["ReturnUrl"];
        if (String.IsNullOrEmpty(returnUrl))
        {
            returnUrl = "~/Mobile/";
        }
        LoginUser.DestinationPageUrl = returnUrl;

        // (the following line is already present by default)
        RegisterHyperLink.NavigateUrl = "Register.aspx?ReturnUrl="
                                        + HttpUtility.UrlEncode(returnUrl);
    }
}
```

This code assumes your page has a Login server control called LoginUser, as in the default project template.

Working with Output Caching

If you're using output caching, beware that by default it's possible for a desktop user to visit a certain URL (causing its output to be cached), followed by a mobile user who then receives the cached desktop output. This warning applies whether you're just varying your master page by device type, or implementing totally separate Web Forms per device type.

To avoid the problem, you can instruct ASP.NET to vary the cache entry according to whether the visitor is using a mobile device. Add a VaryByCustom parameter to your page's OutputCache declaration as follows:

```
<%@ OutputCache VaryByParam="*" Duration="60" VaryByCustom="isMobileDevice" %>
```

Next, define *isMobileDevice* as a custom cache parameter by adding the following method override to your Global.asax.cs file:

```
public override string GetVaryByCustomString(HttpContext context, string custom)
{
    if (string.Equals(custom, "isMobileDevice", StringComparison.OrdinalIgnoreCase))
        return context.Request.Browser.IsMobileDevice.ToString();

    return base.GetVaryByCustomString(context, custom);
}
```

This will ensure that mobile visitors to the page don't receive output previously put into the cache by a desktop visitor.

A working example

To see these techniques in action, download this white paper's code samples. The Web Forms sample application automatically redirects mobile users to a set of mobile-specific pages in a subfolder called Mobile. The markup and styling of those pages is better optimized for mobile browsers, as you can see from the following screenshots:

Windows Phone 7 **Opera Mobile**
(using same resolution as HTC Hero)

For more tips about optimizing your markup and CSS for mobile browsers, see the section "Styling mobile pages for mobile browsers" later in this document.

How ASP.NET MVC applications can present mobile-specific pages

Since the Model-View-Controller pattern decouples application logic (in controllers) from presentation logic (in views), you can choose from any of the following approaches to handling mobile support in server-side code:

1. ***Use the same controllers and views for both desktop and mobile browsers, but render the views with different Razor layouts depending on the device type.*** This option works best if you're displaying identical data on all devices, but simply want to supply different CSS stylesheets or change a few top-level HTML elements for mobiles.
2. ***Use the same controllers for both desktop and mobile browsers, but render different views depending on the device type.*** This option works best if you're displaying roughly the same data and providing the same workflows for end users, but want to render very different HTML markup to suit the device being used.
3. ***Create separate areas for desktop and mobile browsers, implementing independent controllers and views for each.*** This option works best if you're displaying very different screens, containing different information and leading the user through different workflows optimized for their device type. It may mean some repetition of code, but you can minimize that by factoring out common logic into an underlying layer or service.

If you want to take the **first** option and vary only the Razor layout per device type, it's very easy. Just modify your _ViewStart.cshtml file as follows:

```
@{
    Layout = Request.Browser.IsMobileDevice ? "~/Views/Shared/_LayoutMobile.cshtml"
                                            : "~/Views/Shared/_Layout.cshtml";
}
```

Now you can create a mobile-specific layout called _LayoutMobile.cshtml with a page structure and CSS rules optimized for mobile devices.

If you want to take the **second** option render totally different views according to the visitor's device type, see Scott Hanselman's blog post.

The rest of this paper focuses on the **third** option – creating separate controllers *and* views for mobile devices – so

you can control exactly what subset of functionality is offered for mobile visitors.

Setting up a Mobile area within your ASP.NET MVC application

You can add an area called "Mobile" to an existing ASP.NET MVC application in the normal way: right-click on your project name in Solution Explorer, then choose Add à Area. You can then add controllers and views as you would for any other area within an ASP.NET MVC application. For example, add to your Mobile area a new controller called HomeController to act as a homepage for mobile visitors.

Ensuring the URL /Mobile reaches the mobile homepage

If you want the URL /Mobile to reach the Index action on HomeController inside your Mobile area, you will need to make two small changes to your routing configuration. First, update your MobileAreaRegistration class so that HomeController is the default controller in your Mobile area, as shown in the following code:

```
public override void RegisterArea(AreaRegistrationContext context)
{
    // By default there is no "controller" parameter in the following line.
    // Add one referencing "Home" as shown.
    context.MapRoute(
        "Mobile_default",
        "Mobile/{controller}/{action}/{id}",
        new { controller = "Home", action = "Index", id = UrlParameter.Optional }
    );
}
```

This means the mobile homepage will now be located at /Mobile, rather than /Mobile/Home, because "Home" is now the implicitly default controller name for mobile pages.

Next, note that by adding a second HomeController to your application (i.e., the mobile one, in addition to the existing desktop one), you'll have broken your regular desktop homepage. It will fail with the error "*Multiple types were found that match the controller named 'Home'*". To resolve this, update your top-level routing configuration (in Global.asax.cs) to specify that your desktop HomeController should take priority when there's ambiguity:

```
public static void RegisterRoutes(RouteCollection routes)
{
    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        "Default",
        "{controller}/{action}/{id}",
        new { controller = "Home", action = "Index", id = UrlParameter.Optional },
        // Add the namespace of your desktop controllers here
        new[] { "YourApplication.Controllers" }
    );
}
```

Now the error will go away, and the URL http://*yoursite*/ will reach the desktop homepage, and http://*yoursite*/mobile/ will reach the mobile homepage.

Redirecting mobile visitors to your mobile area

There are many different extensibility points in ASP.NET MVC, so there are many possible ways to inject redirection logic. One neat option is to create a filter attribute, [RedirectMobileDevicesToMobileArea], that performs a redirection if the following conditions are met:

1. It's the first request in the user's session (i.e., Session.IsNewSession equals true)
2. The request comes from a mobile browser (i.e., Request.Browser.IsMobileDevice equals true)
3. The user is not already requesting a resource in the mobile area (i.e., the *path* part of the URL does not begin with /Mobile)

The downloadable sample included with this white paper includes an implementation of this logic. It's implemented as an authorization filter, derived from AuthorizeAttribute, which means it can work correctly even if you are using output caching (otherwise, if a desktop visitor first accesses a certain URL, the desktop output might be cached and then served to subsequent mobile visitors).

As it's a filter, you can choose either to apply it to specific controllers and actions, e.g.,

```
public class HomeController : Controller
{
    [RedirectMobileDevicesToMobileArea] // Applies just to this action
    public ActionResult Index()
    {
        // ...
    }
}
```

... or you can apply it to all controllers and actions as an MVC 3 *global filter* in your Global.asax.cs file:

```
protected void Application_Start()
{
    // (rest of method unchanged)

    // Using "order" value 1 means it will run after unordered filters
    // associated with specific controllers or actions, so the redirection
    // location can be overridden for specific actions
    GlobalFilters.Filters.Add(new RedirectMobileDevicesToMobileAreaAttribute(), 1);
}
```

The downloadable sample also demonstrates how you can create subclasses of this attribute that redirect to specific locations within your mobile area. This means, for example, you can:

- Register a global filter as shown above that sends mobile visitors to the mobile homepage by default.
- Also apply a special [RedirectMobileDevicesToMobileProductPage] filter to a "view product" action that takes mobile visitors to the mobile version of whatever product page they had requested.
- Also apply other special subclasses of the filter to specific actions, redirecting mobile visitors to the equivalent mobile page

Configuring Forms Authentication to respect your mobile pages

If you're using Forms Authentication, you should note that when a user needs to log in, it automatically redirects the user to a single specific "log on" URL, which by default is `/Account/LogOn`. This means that mobile users may be redirected to your desktop "log on" action.

To avoid this problem, add logic to your desktop "log on" action so that it redirects mobile users again to a mobile "log on" action. If you're using the default ASP.NET MVC application template, update AccountController's LogOn action as follows:

```
public ActionResult LogOn()
{
    string returnUrl = Request.QueryString["ReturnUrl"];
    if ((returnUrl != null) && returnUrl.StartsWith("/Mobile/",
                                StringComparison.OrdinalIgnoreCase))
    {
        return RedirectToAction("LogOn", "Account",
                                 new { Area = "Mobile", ReturnUrl = returnUrl });
    }
    return View();
}
```

... and then implement a suitable mobile-specific "log on" action on a controller called AccountController in your Mobile area.

Working with Output Caching

If you're using the [OutputCache] filter, you must force the cache entry to vary by device type. For example, write:

```
[OutputCache(Duration = 60, VaryByParam = "*", VaryByCustom = "isMobileDevice")]
```

Then, add the following method to your Global.asax.cs file:

```
public override string GetVaryByCustomString(HttpContext context, string custom)
{
    if (string.Equals(custom, "isMobileDevice", StringComparison.OrdinalIgnoreCase))
        return context.Request.Browser.IsMobileDevice.ToString();

    return base.GetVaryByCustomString(context, custom);
}
```

This will ensure that mobile visitors to the page don't receive output previously put into the cache by a desktop visitor.

A working example

To see these techniques in action, download this white paper's code associated samples. The sample includes an ASP.NET MVC 3 (Release Candidate) application enhanced to support mobile devices using the methods described above.

Further guidance and suggestions

The following discussion applies both to Web Forms and MVC developers who are using the techniques covered in this document.

Enhancing your redirection logic using 51Degrees.mobi Foundation

The redirection logic shown in this document may be perfectly sufficient for your application, but it won't work if you need to disable sessions, or with mobile browsers that reject cookies (these can't have sessions), because it won't know whether a given request is the first one from that visitor.

You already learned how the open source 51Degrees.mobi Foundation can improve the accuracy of ASP.NET's browser detection. It also has a built-in ability to redirect mobile visitors to specific locations configured in Web.config. It's able to work without depending on ASP.NET Sessions (and hence cookies) by storing a temporary log of hashes of visitors' HTTP headers and IP addresses, so it knows whether or not each request is the first one from a given vistor.

The following element added to the fiftyOne section of the web.config file will redirect the first request from a detected mobile device to the page ~/Mobile/Default.aspx. Any requests to pages under the Mobile folder will *not* be redirected, regardless of device type. If the mobile device has been inactive for a period of 20 minutes or more the device will be forgotten and subsequent requests will be treated as new ones for the purposes of redirection.

```
<redirect firstRequestOnly="true"
          mobileHomePageUrl="~/Mobile/Default.aspx"
          timeout="20"
          devicesFile="~/App_Data/Devices.dat"
          mobilePagesRegex="/Mobile/" />
```

For more details, see 51degrees.mobi Foundation documentation.

> **NOTE**
> You *can* use 51Degrees.mobi Foundation's redirection feature on ASP.NET MVC applications, but you will need to define your redirection configuration in terms of plain URLs, not in terms of routing parameters or by putting MVC filters on actions. This is because (at the time of writing) 51Degrees.mobi Foundation does not recognize filters or routing.

Disabling Transcoders and Proxy Servers

Mobile network operators have two broad objectives in their approach to the mobile internet:

1. Provide as much relevant content as possible
2. Maximize the number of customers who can share the limited radio network bandwidth

Since most web pages were designed for large desktop-sized screens and fast fixed-line broadband connections, many operators use *transcoders* or *proxy servers* that dynamically alter web content. They may modify your HTML markup or CSS to suit smaller screens (especially for "feature phones" that lack the processing power to handle complex layouts), and they may recompress your images (significantly reducing their quality) to improve page delivery speeds.

But if you've taken the effort to produce a mobile-optimized version of your site, you probably don't want the network operator to interfere with it any further. You can add the following line to the Page_Load event in any ASP.NET Web Form:

```
Response.Cache.SetNoTransforms();
```

Or, for an ASP.NET MVC controller, you could add the following method override so that it applies to all actions on that controller:

```
protected override void OnActionExecuting(ActionExecutingContext filterContext)
{
    filterContext.HttpContext.Response.Cache.SetNoTransforms();
}
```

The resulting HTTP message informs W3C compliant transcoders and proxies not to alter content. Of course, there is no guarantee that mobile network operators will respect this message.

Styling mobile pages for mobile browsers

It's beyond the scope of this document to describe in great detail what kinds of HTML markup work correctly or which web design techniques maximize usability on particular devices. It's up to you to find a sufficiently simple layout, optimized for a mobile-sized screen, without using unreliable HTML or CSS positioning tricks. One important technique worth mentioning, however, is the *viewport meta tag*.

Certain modern mobile browsers, in an effort display web pages meant for desktop monitors, render the page on a virtual canvas, also called "viewport" (e.g., the virtual viewport is 980 pixels wide on iPhone, and 850 pixels wide on Opera Mobile by default) and then scale the result down to fit onto the screen's physical pixels. The user can then zoom in and pan around that viewport. This has the advantage that it lets the browser display the page in its intended layout, but it's also has the disadvantage that it forces zooming and panning, which is inconvenient for the user. If you're designing for mobile, it's better to design for a narrow screen so that no zooming or horizontal scrolling is necessary.

A way to tell the mobile browser how wide the viewport should be is through the nonstandard *viewport* meta tag. For example, if you add the following to your page's HEAD section,

```
<meta name="viewport" content="width=480">
```

... then supporting smartphone browsers will lay out the page on a 480-pixel wide virtual canvas. This means that if your HTML elements define their widths in percentage terms, the percentages will be interpreted with respect to this 480-pixel width, not the default viewport width. As a result, the user is less likely to have to zoom and pan horizontally – considerably improving the mobile browsing experience.

If you want the viewport width to match the device's physical pixels, you can specify the following:

```
<meta name="viewport" content="width=device-width">
```

For this to work correctly, you must not explicitly force elements to exceed that width (e.g., using a *width* attribute or CSS property), otherwise the browser will be forced to use a larger viewport regardless. See also: more details about the nonstandard viewport tag.

Most modern smartphones support *dual orientation*: they can be held in either portrait or landscape mode. So, it's important not to make assumptions about the screen width in pixels. Don't even assume that the screen width is fixed, because the user can re-orient their device while they are on your page.

Older Windows Mobile and Blackberry devices may also accept the following meta tags in the page header to inform them content has been optimized for mobile and therefore should not be transformed.

```
<meta name="MobileOptimized" content="width" />
<meta name="HandheldFriendly" content="true" />
```

Additional Resources

For a list of mobile device emulators and simulators you can use to test your mobile ASP.NET web application, see the page Simulate popular mobile devices for testing.

Fix for 'Server Application Unavailable' Error after Applying Security Update for IE

2/20/2020 • 3 minutes to read • Edit Online

> This paper describes the patch that fixes an issue with the MS03-32 Security Update for Internet Explorer that affects ASP.NET 1.0 applications running on Windows XP Professional.
>
> Applies to ASP.NET 1.0 and Windows XP Professional.

Microsoft identified an issue with the MS03-32 Security Update for Internet Explorer security patch and ASP.NET 1.0 running on Windows XP. This patch can be installed manually or by obtaining recent critical updates from the Windows Update site.

The symptom of this issue is that after installing the patch on a Windows XP machine, all requests to ASP.NET applications running on the local IIS 5.1 web server result in an error message saying "Server Application Unavailable". Requests to remote web servers are unaffected.

This issue only impacts installations running ASP.NET 1.0 on Windows XP. It does not impact machines running Windows 2000 or Windows Server 2003. It also does not impact machines running Windows XP with ASP.NET 1.1 installed.

Please note that this issue **is not** a security bug with ASP.NET. It **does not** open up or allow any malicious attacks against an ASP.NET application or server. Instead, it is purely a functional bug caused by the patch itself.

We are working hard on a permanent solution for this issue. In the meantime, you can execute the following batch file as a workaround for the issue. The batch file does the following:

1. Stops the IIS and ASP.NET state services
2. Deletes and recreates the ASPNET account with a known temporary password
3. Uses the Windows `runas` command to launch an executable that creates an ASPNET user profile
4. Re-registers ASP.NET. This creates a new random password for the account and applies default ASP.NET access control settings for it
5. Restarts the IIS service

The batch file contains a hardcoded temporary password of "**1pass@word**" which you will be prompted to enter for the runas command when the batch file is run. After the runas command completes, the ASPNET account password is recreated with a strong random value. Note that the batch file may fail if the hardcoded password does not meet the password complexity requirements in your environment. If that's the case, you can change it to another value that is appropriate for your environment.

> *[!IMPORTANT]* If you have added custom access control settings or database account permissions for the ASPNET account, they will need to be recreated after this batch file completes. This is because when the account is recreated, it will get a new security identifier (SID).

> *[!IMPORTANT]* If you are running the ASP.NET worker process with a custom account other than the ASPNET account, then you should not run this batch file. Instead, you should log in interactively or use the runas command with that account which will create a user profile for that account.

The batch file is included in the self-extracting archive below. To use it:

1. You must be running as an account with Administrator privileges

2. Download and open the self-extracting executable file
3. Extract the contents to c:\
4. Select Run... from the start menu, and enter `cmd.exe`
5. In the open command windows, type `c:\fixup.cmd`.
6. When prompted, enter **1pass@word** as the password.
7. If you have previously custom access control settings or database account permissions for the ASPNET account, you'll need to re-apply these settings now.

Many apologies for the inconvenience that this has caused. We'll post additional information as it becomes available.

The matrix below details platforms and versions impacted by this issue.

.NET FRAMEWORK	PLATFORM	AFFECTED
Version 1.0	Windows 2000 Professional	No
Version 1.0	Windows 2000 Server	No
Version 1.0	Windows XP Professional	Yes
Version 1.0	Windows Server 2003	No
Version 1.0	Windows XP Home with Cassini	No
Version 1.1	Windows 2000 Professional	No
Version 1.1	Windows 2000 Server	No
Version 1.1	Windows XP Professional	No
Version 1.1	Windows Server 2003	No
Version 1.1	Windows XP Home with Cassini	No

Thanks,
The ASP.NET Team

ASP.NET Side-by-Side Execution of .NET Framework 1.0 and 1.1

2/20/2020 • 5 minutes to read • Edit Online

This whitepaper describes how to install both .NET 1.0 and .NET 1.1 on your machine, allowing an ASP.NET Web application to run on either version of the framework.

Applies to ASP.NET 1.0 and ASP.NET 1.1.

In ASP.NET, applications are said to be running side by side when they are installed on the same computer, but use different versions of the .NET Framework. The following topic describes how to configure ASP.NET applications for side-by-side execution and provides detailed steps to:

- Maintain your Web application's mapping to .NET Framework version 1.0 during installation
- Map a Web application to a specific version of the .NET Framework
- Find the version of the .NET Framework that a Web site is using

Traditionally, when a component or application is updated on a computer, the older version is removed and replaced with the newer version. If the new version is not compatible with the previous version, this usually breaks other applications that use the component or application. The .NET Framework provides support for side-by-side execution, which allows multiple versions of an assembly or application to be installed on the same computer at the same time. Because multiple versions can be installed simultaneously, managed applications can select which version to use without affecting applications that use a different version.

By default, during the installation of the .NET Framework version 1.1, all existing ASP.NET applications are automatically reconfigured to use the latest version of the .NET Framework. If you do not want your ASP.NET applications to default to .NET Framework 1.1, click here to learn how to prevent this during installation.

If you update your Web server to .NET Framework 1.1 and want one or more Web applications to run .NET Framework 1.0, you need to update the Internet Information Services (IIS) Script Map. The script mapping is the mechanism to map the .aspx file extension for a specific Web application to a version of the .NET Framework. Click here to learn how to map a Web application to a specific version of the .NET Framework.

You can use the Internet Information Manger or the ASP.NET IIS Registration Tool (Aspnet_regiis.exe) to find which .NET Framework version is running a particular Web application. Click here to learn how to find the version of the .NET Framework that a Web site is using.

One import consideration when migrating to .NET Framework 1.1 is that each version of the .NET Framework uses its own Machine.config file. As a result, if a Web administrator has made changes to the Machine.config file, those changes must be migrated to the .NET Framework 1.1 Machine.config file.

Maintaining your Web application's mapping to .NET Framework 1.0 during installation

By default, all existing ASP.NET applications are automatically reconfigured during installation to use the newer version of the .NET Framework. Using the newer version of the .NET Framework, applications can take full advantage of improvements and new features included in the new release. At the same time, the Web administrator, who might want granular control over which applications are updated, can prevent the automatic remapping of all existing ASP.NET applications during installation of the .NET Framework.

To prevent the automatic remapping of the entire ASP.NET application to the newer version of the .NET Framework, the Web administrator can use the /noaspupgrade command-line option with the Dotnetfx.exe setup program.

To prevent total remapping of ASP.NET application to newer version

1. Go to **Start**.
2. Click on **run**.
3. Type **cmd**.
4. Click **OK**.

5. From the command prompt, type the following line to start the installation of the .NET Framework: **Dotnetfx.exe /c:"install /noaspupgrade?**.

6. Click **Yes** in the Microsoft .NET Framework 1.1 Setup. This will start the setup process of the .NET Framework 1.1.

Map a Web application to a specific version of the .NET Framework

Each version of the .NET Framework includes a version of the ASP.NET IIS Registration Tool (Aspnet_regiis.exe). This tool enables administrators to specify that a Web application be run under a particular version of the .NET Framework. This is referred to as mapping a Web application to a version of the .NET Framework. Administrators must select the Aspnet_regiis.exe that corresponds to the version of the .NET Framework that will be associated

with the Web application. For example, an administrator who wants to specify that a Web site use .NET Framework 1.1 must use the Aspnet_regiis.exe that comes with .NET Framework 1.1.

The Aspnet_regiis.exe for version 1.0 is located at:

- C:\WINDOWS\Microsoft.NET\Framework**v1.0.3705**\aspnet_regiis

The Aspnet_regiis.exe for version 1,1 is located at:

- C:\WINDOWS\Microsoft.NET\Framework**v1.1.4322**\aspnet_regiis

The Aspnet_regiis.exe provides two options for script mapping a Web application:

- **-s** sets the script map in the path and in its child directories.
- **-sn** sets the script map in the path only.

The path defines the Web application IIS metadata path, which is defined in the form of W3SVC/ROOT/{WebSiteNumber}/{Application_Name}. For example, for a Web application called Portal located under the default Web site, the metabase path is W3SVC/1/ROOT/Portal.

Note You can also use a tool called the Metabase Editor to get the metabase path. You can download this tool from the Microsoft Support site at https://support.microsoft.com/default.aspx?scid=kb;en-us;232068.

- Run Aspnet_regiis.exe -s W3SVC/1/ROOT/Portal to update the portal IIS script map and its subapplication.

- Run Aspnet_regiis.exe -sn W3SVC/1/ROOT/Portal to update the portal IIS script map, without affecting applications in the portal?s subdirectories.

Find the .NET Framework version that a Web application is using

An administrator can use the Internet Service Manager to find which version of the .NET Framework runs a Web site. Different operating system versions launch the Internet Service Manager differently. To start the service manager, follow the steps listed below.

To start Internet Service Manager

1. Go to **Start**.
2. Click on **run**.
3. Type **inetmgr**.

4. From the Internet Service Manager, select the Web application whose version of the .NET Framework you want to know.

5. Right-click on the Web application, and click on **Properties**.

6. From the Property window, select **Configuration**.

7. From the application mapping table, select **.aspx**, and click **Edit**.

8. From the **Executable** text box, look at the version directory by scrolling. If the version directory is v.1.1.4322, the application is mapped to .NET Framework 1.1. Conversely, if the version directory is v1.0.3705, the application is mapped to .NET Framework 1.0.

ASP.NET MVC 4

2/20/2020 • 19 minutes to read • Edit Online

This document describes the release of ASP.NET MVC 4 .

- Installation Notes
- Documentation
- Support
- Software Requirements
- New Features in ASP.NET MVC 4
  - ASP.NET Web API
  - Enhancements to Default Project Templates
  - Mobile Project Template
  - Display Modes
  - jQuery Mobile, the View Switcher, and Browser Overriding
  - Task Support for Asynchronous Controllers
  - Azure SDK
  - Database Migrations
  - Empty Project Template
  - Add Controller to any project folder
  - Bundling and Minification
  - Enabling Logins from Facebook and Other Sites Using OAuth and OpenID
- Upgrading an ASP.NET MVC 3 Project to ASP.NET MVC 4
- Changes from ASP.NET MVC 4 Release Candidate
- Known Issues and Breaking Changes

Installation Notes

ASP.NET MVC 4 for Visual Studio 2010 can be installed from the ASP.NET MVC 4 home page using the Web Platform Installer.

We recommend uninstalling any previously installed previews of ASP.NET MVC 4 prior to installing ASP.NET MVC 4. You can upgrade the ASP.NET MVC 4 Beta and Release Candidate to ASP.NET MVC 4 without uninstalling.

This release is not compatible with any preview releases of .NET Framework 4.5. You must separately upgrade the any installed preview releases of .NET Framework 4.5 to the final version prior to installing ASP.NET MVC 4.

ASP.NET MVC 4 can be installed and run side-by-side with ASP.NET MVC 3.

Documentation

Documentation for ASP.NET MVC is available on the MSDN website at the following URL:

https://go.microsoft.com/fwlink/?LinkID=243043

Tutorials and other information about ASP.NET MVC are available on the MVC 4 page of the ASP.NET website (https://www.asp.net/mvc/mvc4).

Support

ASP.NET MVC 4 is fully supported. If you have questions about working with this release you can also post them to the ASP.NET MVC forum (https://forums.asp.net/1146.aspx), where members of the ASP.NET community are frequently able to provide informal support.

Software Requirements

The ASP.NET MVC 4 components for Visual Studio require PowerShell 2.0 and either Visual Studio 2010 with Service Pack 1 or Visual Web Developer Express 2010 with Service Pack 1.

New Features in ASP.NET MVC 4

This section describes features that have been introduced in the ASP.NET MVC 4 release.

ASP.NET Web API

ASP.NET MVC 4 includes ASP.NET Web API, a new framework for creating HTTP services that can reach a broad range of clients including browsers and mobile devices. ASP.NET Web API is also an ideal platform for building RESTful services.

ASP.NET Web API includes support for the following features:

- **Modern HTTP programming model:** Directly access and manipulate HTTP requests and responses in your Web APIs using a new, strongly typed HTTP object model. The same programming model and HTTP pipeline is symmetrically available on the client through the new *HttpClient* type.
- **Full support for routes:** ASP.NET Web API supports the full set of route capabilities of ASP.NET Routing, including route parameters and constraints. Additionally, use simple conventions to map actions to HTTP methods.
- **Content negotiation:** The client and server can work together to determine the right format for data being returned from a web API. ASP.NET Web API provides default support for XML, JSON, and Form URL-encoded formats and you can extend this support by adding your own formatters, or even replace the default content negotiation strategy.
- **Model binding and validation:** Model binders provide an easy way to extract data from various parts of an HTTP request and convert those message parts into .NET objects which can be used by the Web API actions. Validation is also performed on action parameters based on data annotations.
- **Filters:** ASP.NET Web API supports filters including well-known filters such as the *[Authorize]* attribute. You can author and plug in your own filters for actions, authorization and exception handling.
- **Query composition:** Use the *[Queryable]* filter attribute on an action that returns *IQueryable* to enable support for querying your web API via the OData query conventions.
- **Improved testability:** Rather than setting HTTP details in static context objects, web API actions work with instances of *HttpRequestMessage* and *HttpResponseMessage*. Create a unit test project along with your Web API project to get started quickly writing unit tests for your Web API functionality.
- **Code-based configuration:** ASP.NET Web API configuration is accomplished solely through code, leaving your config files clean. Use the provided service locator pattern to configure extensibility points.
- **Improved support for Inversion of Control (IoC) containers:** ASP.NET Web API provides great support for IoC containers through an improved dependency resolver abstraction
- **Self-host:** Web APIs can be hosted in your own process in addition to IIS while still using the full power of routes and other features of Web API.
- **Create custom help and test pages:** You now can easily build custom help and test pages for your web

APIs by using the new *IApiExplorer* service to get a complete runtime description of your web APIs.

- **Monitoring and diagnostics:** ASP.NET Web API now provides light weight tracing infrastructure that makes it easy to integrate with existing logging solutions such as System.Diagnostics, ETW and third party logging frameworks. You can enable tracing by providing an *ITraceWriter* implementation and adding it to your web API configuration.
- **Link generation:** Use the ASP.NET Web API *UrlHelper* to generate links to related resources in the same application.
- **Web API project template:** Select the new Web API project form the New MVC 4 Project wizard to quickly get up and running with ASP.NET Web API.
- **Scaffolding:** Use the **Add Controller** dialog to quickly scaffold a web API controller based on an Entity Framework based model type.

For more details on ASP.NET Web API please visit https://www.asp.net/web-api.

Enhancements to Default Project Templates

The template that is used to create new ASP.NET MVC 4 projects has been updated to create a more modern-looking website:

In addition to cosmetic improvements, there's improved functionality in the new template. The template employs a technique called adaptive rendering to look good in both desktop browsers and mobile browsers without any customization.

To see adaptive rendering in action, you can use a mobile emulator or just try resizing the desktop browser window to be smaller. When the browser window gets small enough, the layout of the page will change.

Mobile Project Template

If you're starting a new project and want to create a site specifically for mobile and tablet browsers, you can use the new Mobile Application project template. This is based on jQuery Mobile, an open-source library for building touch-optimized UI:

This template contains the same application structure as the Internet Application template (and the controller code is virtually identical), but it's styled using jQuery Mobile to look good and behave well on touch-based mobile devices. To learn more about how to structure and style mobile UI, see the jQuery Mobile project website.

If you already have a desktop-oriented site that you want to add mobile-optimized views to, or if you want to create a single site that serves differently styled views to desktop and mobile browsers, you can use the new Display Modes feature. (See the next section.)

Display Modes

The new Display Modes feature lets an application select views depending on the browser that's making the request. For example, if a desktop browser requests the Home page, the application might use the Views\Home\Index.cshtml template. If a mobile browser requests the Home page, the application might return the Views\Home\Index.mobile.cshtml template.

Layouts and partials can also be overridden for particular browser types. For example:

- If your Views\Shared folder contains both the _Layout.cshtml and _Layout.mobile.cshtml templates, by default the application will use _Layout.mobile.cshtml during requests from mobile browsers and _Layout.cshtml during other requests.
- If a folder contains both _MyPartial.cshtml and _MyPartial.mobile.cshtml, the instruction @Html.Partial("_MyPartial") will render _MyPartial.mobile.cshtml during requests from mobile browsers, and _MyPartial.cshtml during other requests.

If you want to create more specific views, layouts, or partial views for other devices, you can register a new

DefaultDisplayMode instance to specify which name to search for when a request satisfies particular conditions. For example, you could add the following code to the *Application_Start* method in the Global.asax file to register the string "iPhone" as a display mode that applies when the Apple iPhone browser makes a request:

```
DisplayModeProvider.Instance.Modes.Insert(0, new
DefaultDisplayMode("iPhone")
{
    ContextCondition = (context => context.GetOverriddenUserAgent().IndexOf
        ("iPhone", StringComparison.OrdinalIgnoreCase) >= 0)
});
```

After this code runs, when an Apple iPhone browser makes a request, your application will use the Views\Shared_Layout.iPhone.cshtml layout (if it exists). For more information on Display Mode, see ASP.NET MVC 4 Mobile Features. Applications using DisplayModeProvider should install the Fixed DisplayModes NuGet package. The ASP.NET Fall 2012 Update includes the Fixed DisplayModes NuGet package in the new project templates. See ASP.NET MVC 4 Mobile Caching Bug Fixedd for details on the fix.

jQuery Mobile and Mobile Features

For information on building Mobile applications with ASP.NET MVC 4 using jQuery Mobile, see the tutorial ASP.NET MVC 4 Mobile Features.

Task Support for Asynchronous Controllers

You can now write asynchronous action methods as single methods that return an object of type *Task* or *Task<ActionResult>*.

For more information see Using Asynchronous Methods in ASP.NET MVC 4.

Azure SDK

ASP.NET MVC 4 supports the 1.6 and newer releases of the Windows Azure SDK.

Database Migrations

ASP.NET MVC 4 projects now include Entity Framework 5. One of the great features in Entity Framework 5 is support for database migrations. This feature enables you to easily evolve your database schema using a code-focused migration while preserving the data in the database. For more information on database migrations, see Adding a New Field to the Movie Model and Table in the Introduction to ASP.NET MVC 4 tutorial.

Empty Project Template

The MVC Empty project template is now truly empty so that you can start from a completely clean slate. The earlier version of the Empty project template has been renamed to Basic.

Add Controller to any project folder

You can now right click and select **Add Controller** from any folder in your MVC project. This gives you more flexibility to organize your controllers however you want, including keeping your MVC and Web API controllers in separate folders.

Bundling and Minification

The bundling and minification framework enables you to reduce the number of HTTP requests that a Web page needs to make by combining individual files into a single, bundled file for scripts and CSS. It can then reduce the overall size of those requests by minifying the contents of the bundle. Minifying can include activities like eliminating whitespace to shortening variable names to even collapsing CSS selectors based on their semantics. Bundles are declared and configured in code and are easily referenced in views via helper methods which can generate either a single link to the bundle or, when debugging, multiple links to the individual contents of the bundle. For more information see Bundling and Minification.

Enabling Logins from Facebook and Other Sites Using OAuth and OpenID

The default templates in ASP.NET MVC 4 Internet Project template now includes support for OAuth and OpenID login using the DotNetOpenAuth library. For information on configuring an OAuth or OpenID provider, see OAuth/OpenID Support for WebForms, MVC and WebPages and the OAuth and OpenID feature documentation in ASP.NET Web Pages.

Upgrading an ASP.NET MVC 3 Project to ASP.NET MVC 4

ASP.NET MVC 4 can be installed side by side with ASP.NET MVC 3 on the same computer, which gives you flexibility in choosing when to upgrade an ASP.NET MVC 3 application to ASP.NET MVC 4.

The simplest way to upgrade is to create a new ASP.NET MVC 4 project and copy all the views, controllers, code, and content files from the existing MVC 3 project to the new project and then to update the assembly references in the new project to match any non-MVC template included assembiles you are using. If you have made changes to the Web.config file in the MVC 3 project, you must also merge those changes into the Web.config file in the MVC 4 project.

To manually upgrade an existing ASP.NET MVC 3 application to version 4, do the following:

1. In all Web.config files in the project (there is one in the root of the project, one in the Views folder, and one in the Views folder for each area in your project), replace every instance of the following text (note: System.Web.WebPages, Version=1.0.0.0 is not found in projects created with Visual Studio 2012):

   ```
   System.Web.Mvc, Version=3.0.0.0
   System.Web.WebPages, Version=1.0.0.0
   System.Web.Helpers, Version=1.0.0.0
   System.Web.WebPages.Razor, Version=1.0.0.0
   ```

   with the following corresponding text:

   ```
   System.Web.Mvc, Version=4.0.0.0
   System.Web.WebPages, Version=2.0.0.0
   System.Web.Helpers, Version=2.0.0.0
   System.Web.WebPages.Razor, Version=2.0.0.0
   ```

2. In the root Web.config file, update the *webPages:Version* element to "2.0.0.0" and add a new *PreserveLoginUrl* key that has the value "true":

   ```
   <appSettings>
     <add key="webpages:Version" value="2.0.0.0" />
     <add key="PreserveLoginUrl" value="true" />
   </appSettings>
   ```

3. In Solution Explorer, right-click on the References and select Manage NuGet Packages. In the left pane, select **Online\NuGet official package source**, then update the following:

   - ASP.NET MVC 4
   - (Optional) jQuery, jQuery Validation and jQuery UI
   - (Optional) Entity Framework
   - (Optonal) Modernizr

4. In Solution Explorer, right-click the project name and then select Unload Project. Then right-click the name again and select Edit *ProjectName*.csproj.

5. Locate the *ProjectTypeGuids* element and replace {E53F8FEA-EAE0-44A6-8774-FFD645390401} with {E3E379DF-F4C6-4180-9B81-6769533ABE47}.

6. Save the changes, close the project (.csproj) file you were editing, right-click the project, and then select Reload Project.

7. If the project references any third-party libraries that are compiled using previous versions of ASP.NET MVC, open the root Web.config file and add the following three *bindingRedirect* elements under the *configuration* section:

```
<configuration>
  <!--... elements deleted for clarity ...-->

  <runtime>
    <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
      <dependentAssembly>
        <assemblyIdentity name="System.Web.Helpers"
             publicKeyToken="31bf3856ad364e35" />
        <bindingRedirect oldVersion="1.0.0.0" newVersion="2.0.0.0"/>
      </dependentAssembly>
      <dependentAssembly>
        <assemblyIdentity name="System.Web.Mvc"
             publicKeyToken="31bf3856ad364e35" />
        <bindingRedirect oldVersion="1.0.0.0-3.0.0.0" newVersion="4.0.0.0"/>
      </dependentAssembly>
      <dependentAssembly>
        <assemblyIdentity name="System.Web.WebPages"
             publicKeyToken="31bf3856ad364e35" />
        <bindingRedirect oldVersion="1.0.0.0" newVersion="2.0.0.0"/>
      </dependentAssembly>
    </assemblyBinding>
  </runtime>
</configuration>
```

Changes from ASP.NET MVC 4 Release Candidate

The release notes for ASP.NET MVC 4 Release Candidate can be found here:

The major changes from ASP.NET MVC 4 Release Candidate in this release are summarized below:

- **Per controller configuration:** ASP.NET Web API controllers can be attributed with a custom attribute that implements *IControllerConfiguration* to setup their own formatters, action selector and parameter binders. The *HttpControllerConfigurationAttribute* has been removed.
- **Per route message handlers:** You can now specify the final message handler in the request chain for a given route. This enables support for ride-along frameworks to use routing to dispatch to their own (non-*IHttpController*) endpoints.
- **Progress notifications:** The *ProgressMessageHandler* generates progress notification for both request entities being uploaded and response entities being downloaded. Using this handler it is possible to keep track of how far you are uploading a request body or downloading a response body.
- **Push content:** The *PushStreamContent* class enables scenarios where a data producer wants to write directly to the request or response(either synchronously or asynchronously) using a stream. When the *PushStreamContent* is ready to accept data it calls out to an action delegate with the output stream. The developer can then write to the stream for as long as necessary and close the stream when writing has completed. The *PushStreamContent* detects the closing of the stream and completes the underlying asynchronous *Task* for writing out the content.
- **Creating error responses:** Use the *HttpError* type to consistently represent error information from such as validation errors and exceptions while still honoring the *IncludeErrorDetailPolicy*. Use the new *CreateErrorResponse* extension methods to easily create error responses with *HttpError* as content. The *HttpError* content is fully content negotiated.
- **MediaRangeMapping removed:** Media type ranges are now handled by the default content negotiator.

- **Default parameter binding for simple type parameters is now [FromUri]:** In previous releases of ASP.NET Web API the default parameter binding for simple type parameters used model binding. The default parameter binding for simple type parameters is now *[FromUri]*.
- **Action selection honors required parameters:** Action selection in ASP.NET Web API will now only select an action if all required parameters that come from the URI are provided. A parameter can be specified as optional by providing a default value for the argument in the action method signature.
- **Customize HTTP parameter bindings:** Use the *ParameterBindingAttribute* to customize the parameter binding for a specific action parameter or use the *ParameterBindingRules* on the *HttpConfiguration* to customize parameter bindings more broadly.
- **MediaTypeFormatter improvements:** Formatters now have access to the full *HttpContent* instance.
- **Host buffering policy selection:** Implement and configure the *IHostBufferPolicySelector* service in ASP.NET Web API to enable hosts to determine the policy for when buffering is to be used.
- **Access client certificates in a host agnostic manner:** Use the *GetClientCertificate* extension method to get the supplied client certificate from the request message.
- **Content negotiation extensibility:** Customize content negotiation by deriving from the *DefaultContentNegotiator* and overriding any aspect of content negotiation that you would like.
- **Support for returning 406 Not Acceptable responses:** You can now return 406 Not Acceptable responses in ASP.NET Web API when a suitable formatter is not found by creating a *DefaultContentNegotiator* with the *excludeMatchOnTypeOnly* parameter set to *true*.
- **Read form data as NameValueCollection or JToken:** You can read form data in the URI query string or in the request body as a *NameValueCollection* using the *ParseQueryString* and *ReadAsFormDataAsync* extension methods respectively. Similarly, you can read form data in the URI query string or in the request body as a *JToken* using the *TryReadQueryAsJson* and *ReadAsAsync*<T> extension methods respectively.
- **Multipart improvements:** It is now possible to write a *MultipartStreamProvider* that is completely tailored to the type of MIME multipart data that it can read and present the result in the optimal way to the user. You can also hook a post processing step on the *MultipartStreamProvider* that allows the implementation to do whatever post processing it wants on the MIME multipart body parts. For example, the *MultipartFormDataStreamProvider* implementation reads the HTML form data parts and adds them to a *NameValueCollection* so they are easy to get at from the caller.
- **Link generation improvements:** The *UrlHelper* no longer depends on *HttpControllerContext*. You can now access the *UrlHelper* from any context where the *HttpRequestMessage* is available.
- **Message handler execution order change:** Message handlers are now executed in the order that they are configured instead of in reverse order.
- **Helper for wiring up message handlers:** The new *HttpClientFactory* that can wire up *DelegatingHandlers* and create an *HttpClient* with the desired pipeline ready to go. It also provides functionality for wiring up with alternative inner handlers (the default is *HttpClientHandler*) as well as do the wiring up when using *HttpMessageInvoker* or another *DelegatingHandler* instead of *HttpClient* as the top-invoker.
- **Support for CDNs in ASP.NET Web Optimization:** ASP.NET Web Optimization now provides support for CDN alternate paths enabling you to specify for each bundle an additional URL which points to that same resource on a content delivery network. Supporting CDNs enables you to get your script and style bundles geographically closer to the end consumers of your Web applications. Production apps should implement a fallback when the CDN is unavailable. Test the fallback.
- **ASP.NET Web API routes and configuration moved to *WebApiConfig.Register* static method that can be resused in test code.** ASP.NET Web API routes previously were added in *RouteConfig.RegisterRoutes* along with the standard MVC routes. The default ASP.NET Web API routes and configuration are now handled in a separate *WebApiConfig.Register* method to facilitate testing.

Known Issues and Breaking Changes

- **The RC and RTM version of ASP.NET MVC 4 incorrectly returned cached desktop views when**

mobile views should be returned.

  - See ASP.NET MVC 4 Mobile Caching Bug Fixed for details on the fix. The fix can be installed from the Fixed DisplayModes NuGet package.

- **Breaking changes in the Razor View Engine**. The following types were removed from *System.Web.Mvc.Razor*:

  - *ModelSpan*
  - *MvcVBRazorCodeGenerator*
  - *MvcCSharpRazorCodeGenerator*
  - *MvcVBRazorCodeParser*

  The following methods were also removed:

  - *MvcCSharpRazorCodeParser.ParseInheritsStatement(System.Web.Razor.Parser.CodeBlockInfo)*
  - *MvcWebPageRazorHost.DecorateCodeGenerator(System.Web.Razor.Generator.RazorCodeGenerator)*
  - *MvcVBRazorCodeParser.ParseInheritsStatement(System.Web.Razor.Parser.CodeBlockInfo)*

- **When WebMatrix.WebData.dll is included in the /bin directory of an ASP.NET MVC 4 apps, it takes over the URL for forms authentication.** Adding the WebMatrix.WebData.dll assembly to your application (for example, by selecting "ASP.NET Web Pages with Razor Syntax" when using the Add Deployable Dependencies dialog) will override the authentication login redirect to /account/logon rather than /account/login as expected by the default ASP.NET MVC Account Controller. To prevent this behavior and use the URL specified already in the authentication section of web.config, you can add an appSetting called PreserveLoginUrl and set it to true:

```
<appSettings>
    <add key="PreserveLoginUrl" value="true"/>
</appSettings>
```

- **The NuGet package manager fails to install when attempting to install ASP.NET MVC 4 for side by side installations of Visual Studio 2010 and Visual Web Developer 2010.** To run Visual Studio 2010 and Visual Web Developer 2010 side by side with ASP.NET MVC 4 you must install ASP.NET MVC 4 after both versions of Visual Studio have already been installed.

- **Uninstalling ASP.NET MVC 4 fails if prerequisites have already been uninstalled.** To cleanly uninstall ASP.NET MVC 4you must uninstall ASP.NET MVC 4 prior to uninstalling Visual Studio.

- **Installing ASP.NET MVC 4 breaks ASP.NET MVC 3 RTM applications.** ASP.NET MVC 3 applications that were created with the RTM release (not with the ASP.NET MVC 3 Tools Update release) require the following changes in order to work side-by-side with ASP.NET MVC 4. Building the project without making these updates results in compilation errors.

  Required updates

  1. In the root Web.config file, add a new *<appSettings>* entry with the key *webPages:Version* and the value *1.0.0.0*.

     ```
     <appSettings>
         <add key="webpages:Version" value="1.0.0.0"/>
         <add key="ClientValidationEnabled" value="true"/>
         <add key="UnobtrusiveJavaScriptEnabled" value="true"/>
     </appSettings>
     ```

  2. In Solution Explorer, right-click the project name and then select Unload Project. Then right-click the name again and select Edit *ProjectName*.csproj.

3. Locate the following assembly references:

```
<Reference Include="System.Web.WebPages"/>
<Reference Include="System.Web.Helpers" />
```

   Replace them with the following:

```
<Reference Include="System.Web.WebPages, Version=1.0.0.0,
Culture=neutral, PublicKeyToken=31bf3856ad364e35, processorArchitecture=MSIL "/>
<Reference Include="System.Web.Helpers, Version=1.0.0.0,
Culture=neutral, PublicKeyToken=31bf3856ad364e35, processorArchitecture=MSIL" />
```

4. Save the changes, close the project (.csproj) file you were editing, and then right-click the project and select Reload.

- **Changing an ASP.NET MVC 4 project to target 4.0 from 4.5 does not update the EntityFramework assembly reference:** If you change an ASP.NET MVC 4 project to target 4.0 after targetting 4.5 the reference to the EntityFramework assembly will still point to the 4.5 version. To fix this issue uninstall and reinstall the EntityFramework NuGet package.
- **403 Forbidden when running an ASP.NET MVC 4 application on Azure after changing to target 4.0 from 4.5:** If you change an ASP.NET MVC 4 project to target 4.0 after targetting 4.5 and then deploy to Azure you may see a 403 Forbidden error at runtime. To workaround this issue add the following to your web.config: `<modules runAllManagedModulesForAllRequests="true" />`
- **Visual Studio 2012 crashes when you type a '' in a string literal in a Razor file.** To work around the issue enter the closing quote of the string literal first.
- **Browsing to "Account/Manage" in the Internet template results in a runtime error for CHS, TRK and CHT languages.** To fix the issue modify the page to separate out *@User.Identity.Name* by puting it as the only content within the ** tag.
- **Google and LinkedIn providers are not supported within Azure Web Sites.** Use alternative authentication providers when deploying to Azure Web Sites.
- **When using UriPathExtensionMapping with IIS 8 Express/IIS, you would receive 404 Not Found errors when you try to use the extension.** The static file handler will interfere with requests to web APIs that use *UriPathExtensionMappings*. Set *runAllManagedModulesForAllRequests=true* in web.config to work around the issue.
- **Controller.Execute method is no longer called.** All MVC controllers are now always executed asynchronously.

Request Validation - Preventing Script Attacks

2/20/2020 • 3 minutes to read • Edit Online

This paper describes the request validation feature of ASP.NET where, by default, the application is prevented from processing unencoded HTML content submitted to the server. This request validation feature can be disabled when the application has been designed to safely process HTML data.

Applies to ASP.NET 1.1 and ASP.NET 2.0.

Request validation, a feature of ASP.NET since version 1.1, prevents the server from accepting content containing un-encoded HTML. This feature is designed to help prevent some script-injection attacks whereby client script code or HTML can be unknowingly submitted to a server, stored, and then presented to other users. We still strongly recommend that you validate all input data and HTML encode it when appropriate.

For example, you create a Web page that requests a user's email address and then stores that email address in a database. If the user enters <SCRIPT>alert("hello from script")</SCRIPT> instead of a valid email address, when that data is presented, this script can be executed if the content was not properly encoded. The request validation feature of ASP.NET prevents this from happening.

Why this feature is useful

Many sites are not aware that they are open to simple script injection attacks. Whether the purpose of these attacks is to deface the site by displaying HTML, or to potentially execute client script to redirect the user to a hacker's site, script injection attacks are a problem that Web developers must contend with.

Script injection attacks are a concern of all web developers, whether they are using ASP.NET, ASP, or other web development technologies.

The ASP.NET request validation feature proactively prevents these attacks by not allowing unencoded HTML content to be processed by the server unless the developer decides to allow that content.

What to expect: Error Page

The screen shot below shows some sample ASP.NET code:

```
<script runat="server">

  Public Sub Button_Click(sender As Object, e As EventArgs)

    ' Set the Label to the value of the textbox
    Label1.Text = TextBox1.Text

  End Sub

</script>

<form runat="server">

  <asp:TextBox id="TextBox1" runat="server" />
  <asp:Button OnClick="Button_Click" runat="server" Text="Click Me!"/>

</form>

You entered: <b><asp:Label id="Label1" runat="server" /></b>
```

Running this code results in a simple page that allows you to enter some text in the textbox, click the button, and display the text in the label control:

However, were JavaScript, such as `<script>alert("hello!")</script>` to be entered and submitted we would get an exception:

The error message states that a 'potentially dangerous Request.Form value was detected' and provides more details in the description as to exactly what occurred and how to change the behavior. For example:

Request validation has detected a potentially dangerous client input value, and processing of the request has been aborted. This value may indicate an attempt to compromise the security of your application, such as a cross-site scripting attack. You can disable request validation by setting `validateRequest=false` in the Page directive or in the configuration section. However, it is strongly recommended that your application explicitly check all inputs in this case.

Disabling request validation on a page

To disable request validation on a page you must set the `validateRequest` attribute of the Page directive to `false` :

```
<%@ Page validateRequest="false" %>
```

Caution

When request validation is disabled, content can be submitted to a page; it is the responsibility of the page developer to ensure that content is properly encoded or processed.

Disabling request validation for your application

To disable request validation for your application, you must modify or create a Web.config file for your application and set the validateRequest attribute of the `<pages />` section to `false` :

```
<configuration>
   <system.web>
      <pages validateRequest="false" />
   </system.web>
</configuration>
```

If you wish to disable request validation for all applications on your server, you can make this modification to your Machine.config file.

Caution

When request validation is disabled, content can be submitted to your application; it is the responsibility of the application developer to ensure that content is properly encoded or processed.

The code below is modified to turn off request validation:

```
<%@ Page Language="VB" validateRequest="false" %>

<script runat="server">

  Public Sub Button_Click(sender As Object, e As EventArgs)

    ' Set the Label to the value of the textbox
    Label1.Text = TextBox1.Text

  End Sub

</script>

<form runat="server">

  <asp:TextBox id="TextBox1" runat="server" />
  <asp:Button OnClick="Button_Click" runat="server" Text="Click Me!"/>

</form>

You entered: <b><asp:Label id="Label1" runat="server" /></b>
```

Now if the following JavaScript was entered into the textbox `<script>alert("hello!")</script>` the result would be:

To prevent this from happening, with request validation turned off, we need to HTML encode the content.

How to HTML encode content

If you have disabled request validation, it is good practice to HTML-encode content that will be stored for future use. HTML encoding will automatically replace any '<' or '>' (together with several other symbols) with their corresponding HTML encoded representation. For example, '<' is replaced by '<' and '>' is replaced by '>'. Browsers use these special codes to display the '<' or '>' in the browser.

Content can be easily HTML-encoded on the server using the `Server.HtmlEncode(string)` API. Content can also be easily HTML-decoded, that is, reverted back to standard HTML using the `Server.HtmlDecode(string)` method.

```
<%@ Page Language="VB" validateRequest="false" %>

<script runat="server">

  Public Sub Button_Click(sender As Object, e As EventArgs)

    ' Set the Label to the value of the textbox
    Label1.Text = Server.HtmlEncode(TextBox1.Text)

  End Sub

</script>

<form runat="server">

  <asp:TextBox id="TextBox1" runat="server" />
  <asp:Button OnClick="Button_Click" runat="server" Text="Click Me!"/>

</form>

You entered: <b><asp:Label id="Label1" runat="server" /></b>
```

ASP.NET Data Access - Recommended Resources

2/20/2020 • 13 minutes to read • Edit Online

This topic provides links to documentation resources about how to access data in ASP.NET web applications, primarily by using the Entity Framework and SQL Server.

If you know a great blog post, stackoverflow thread, or any other link that would be useful, [send us an email](aspnetue@microsoft.com?subject=Data Access Content Map) with the link.

Last updated 4/3/2014

The topic contains the following sections:

- Getting Started with Data Access in ASP.NET
- Using the Entity Framework
  - Using Entity Framework Code First
  - Using Entity Framework Code First Migrations
  - Using Entity Framework Database First or Model First (the EF Designer)
  - Loading Related data in Entity Framework (Lazy Loading, Eager Loading, and Explicit Loading)
  - Optimizing Entity Framework Performance
  - Handling Concurrency in an Entity Framework Application
  - Books about the Entity Framework
  - Additional Entity Framework resources
- Data Binding in ASP.NET Web Forms Applications
  - Using Web Forms Model Binding
  - Using Web Forms Data Source Controls
  - Using Web Forms Data-Bound Controls and Data-Binding Expressions
- Working with SQL Server Databases
  - Working with SQL Server Express LocalDB Databases
  - Working with SQL Server Express Databases
  - Working with Windows Azure SQL Database
  - Choosing between SQL Server and Windows Azure SQL Database
- Working with NoSQL Database Management Systems
- Using LINQ queries in ASP.NET Applications
- Using Dynamic Data scaffolding
- Securing Data Access
- Optimizing Data Access Performance
- Deploying a Database
- Accessing Data through a Web Service
- Additional Resources

Getting Started with Data Access in ASP.NET

- Data Storage Options (Building Real-World Cloud Apps with Windows Azure). Chapter of an e-book about developing for the cloud. Introduces NoSQL databases as an alternative that many developers familiar with relational databases tend to overlook. Presents guidelines on what to think about when choosing relational or NoSQL, or choosing a particular platform.
- ASP.NET Data Access Options (MSDN). An introduction to data access options for relational databases for ASP.NET and guidance on how to choose platforms and access methods that are appropriate for your scenario.
- Relational database. Wikipedia). If you haven't worked with relational databases, see this page for an introduction to relational database terminology and concepts. For an introduction to SQL Server in particular see Working with SQL Server databases later in this topic.

Using the Entity Framework

- Entity Framework Development Approaches (MSDN). Guidance on how to choose an Entity Framework development approach Database First, Model First, or Code First.

Using Entity Framework Code First

The following tutorials offer downloadable sample applications:

- Getting Started with EF 6 using MVC 5. Covers a wide range of Entity Framework Code First scenarios, including Migrations and EF 6 features such as connection resiliency, command interception, and async. This is an updated version of the EF 5 / MVC 4 series. The earlier series includes a tutorial on the repository and unit-of-work patterns that is not included in the new series.
- Introduction to ASP.NET MVC 5. Covers a narrower range of Entity Framework Code First scenarios but does a more comprehensive job of introducing MVC features.
- Model Binding and Web Forms. Uses Code First in a Web Forms application.
- Getting Started with ASP.NET 4.5 Web Forms. An introduction to Web Forms with some coverage of Code First. Uses Model Binding.
- MVC Music Store. Uses Code First in an e-commerce MVC 3 application that also implements membership and authorization. The MVC version and ASP.NET membership (authentication and authorization) system used here are outdated; for more up-to-date information on ASP.NET membership, see https://asp.net/identity.

Other resources:

- Entity Framework - Code First to an Existing Database. MSDN. Video and walkthrough that shows how to use Code First with an existing database.
- Data Developer Center - Entity Framework. MSDN. For a guide to Entity Framework documentation that has been created and maintained by the Entity Framework team, see the Get Started link.

See also Books about the Entity Framework and Additional Entity Framework Resources later in this topic.

Using Entity Framework Code First Migrations

Most of the Code First tutorials listed above cover migrations. See also the following resources.

- ASP.NET Web Deployment using Visual Studio. 2-part tutorial series that shows how to use Code First Migrations to deploy a database.
- Deploy a Secure ASP.NET MVC 5 app with Membership, OAuth, and SQL Database to a Windows Azure Web Site. Microsoft Azure). How to use migrations to deploy membership and application data to Azure.
- Web Deployment Overview for Visual Studio and ASP.NET. See the **Configuring Database Deployment in Visual Studio** section for an explanation of how Code First Migrations is integrated into Visual Studio web deployment features.

- Data Developer Center - Code First Migrations (MSDN). The Entity Framework team's Migrations documentation.
- Migrations Screencast Series. EF blog). Three videos on advanced topics in Code First Migrations.
- Code First Migrations With ASP.NET Web Pages Sites. Mikesdotnetting blog). Shows how to use Code First migrations with an ASP.NET Web Pages site by putting the data context in a Visual Studio class library project.

Using Entity Framework Database First or Model First (the EF Designer)

- Getting Started with Entity Framework 6 Database First using MVC 5. Run a script in Server Explorer to create a database, and then use the Entity Framework designer to create the data model. Shows how to create simple CRUD web pages, and for other data handling functions you can follow one of the Code First tutorials since all EF workflows use the same DbContext API.

The following resources are older. They are useful if you want to use version 4.0 of the Entity Framework, and you want to use a data source control for data binding in a Web Forms application.

- Getting Started with the Entity Framework 4.0. Shows how to use the **EntityDataSource** control.
- Continuing with the Entity Framework(Shows how to use the **ObjectDataSource** Control. Includes a tutorial on concurrency handling, a tutorial on EF performance, and a tutorial on what's new in EF 4.0.

Handling related data in Entity Framework (Lazy Loading, Eager Loading, and Explicit Loading)

- Reading Related Data with the Entity Framework in an ASP.NET MVC Application. Code First, MVC sample application. The methods shown apply also to Web Forms model binding and the Database First workflow.
- Data Developer Center - Loading Related Entities (MSDN). The Entity Framework team's documentation about loading related data.

Optimizing Entity Framework performance

- Advanced Entity Framework Scenarios for an ASP.NET Application. Shows how to execute your own SQL statements or call your own stored procedures, how to disable change detection, and how to disable validation when saving changes.
- Performance Considerations for Entity Framework 5 (MSDN).
- Performance Considerations (Entity Framework) (MSDN).
- Maximizing Performance with the Entity Framework in an ASP.NET Web Application. Applies to Entity Framework 4.0.
- See also Optimizing ASP.NET data access later in this topic.

Handling Concurrency in an Entity Framework Application

- Handling Concurrency with the Entity Framework in an ASP.NET MVC Application. Code First, DbContext API, using an MVC sample application.
- Data Developer Center – Optimistic Concurrency Patterns (MSDN). The Entity Framework team's concurrency documentation.
- Handling Concurrency with the Entity Framework in an ASP.NET Web Application. Applies to Entity Framework 4.0. Database First, ObjectContext API, using a Web Forms sample application.

Books about the Entity Framework

- Programming Entity Framework: DbContext by Julie Lerman and Rowan Miller.
- Programming Entity Framework: Code First by Julie Lerman and Rowan Miller.

Both of these books are up-to-date with current recommended techniques. They provide a more comprehensive yet easy-to-follow introduction to the Entity Framework than anything available on the Internet. Another book, Programming Entity Framework by Julie Lerman, is larger and more comprehensive but it is older and many of the techniques it covers are no longer the recommended way to use the Entity

Framework. See also the list of books recommended by the Entity Framework team at Data Developer Center - Books on the MSDN site.

Other Entity Framework Resources

- Entity Framework (ADO.NET) team blog. One of the best resources for the most current information and announcements of new enhancements. For other EF-related blogs, see the Blogroll at Get Started with Entity Framework.
- MSDN Magazine. See the **Data Points** column, which is frequently about topics related to the Entity Framework.

Data Binding in ASP.NET Web Forms Applications

- ASP.NET Web Forms Data Access Options (MSDN).

Using Web Forms Model Binding

- Model Binding and Web Forms. Tutorial series using EF Code First.
- Web Forms Model Binding Part 1: Selecting Data (Scott Guthrie's blog). In these older blog posts, the property that is currently named ItemType was named ModelType, but otherwise the information they contain is valid.
- Web Forms Model Binding Part 2: Filtering Data (Scott Guthrie's blog).
- Web Forms Model Binding Part 3: Updating and Validation (Scott Guthrie's blog).
- ASP.NET 4.5 Web Forms Model Binding. (video).
- Model Binding Part 1 - Selecting Data (video).
- Model Binding Part 2 - Filtering (video).
- Getting Started with ASP.NET 4.5 Web Forms - Display Data Items and Details.

Using Web Forms Data Source Controls

- Data Source Web Server Controls (MSDN).
- Announcing the release of Dynamic Data provider and EntityDataSource control for Entity Framework 6 (Microsoft Web Development blog).

Using Web Forms Data-Bound Controls and Data-Binding Expressions

- Model Binding and Web Forms. Tutorial series that uses EF Code First.
- Getting Started with ASP.NET 4.5 Web Forms - Display Data Items and Details.
- Strongly Typed Data Controls (Scott Guthrie's blog).
- Strongly Typed Data Controls (video).
- ASP.NET 4.5 Web Forms Strong Typed Data Controls (video).
- Data-Bound Web Server Controls (MSDN).
- Data-Binding Expressions Overview (MSDN). This page only covers **Eval** and **Bind**; it has not been updated to include **Item** and **BindItem**.

Working with SQL Server Databases

- SQL Server Database Features (MSDN). For a general introduction to a wide variety of SQL Server topics, see the entries under this one in the TOC.
- SQL Server Editions (MSDN). A summary of the available SQL Server editions, with links to more information about each one.)
- SQL Server Connection Strings for ASP.NET Web Applications (MSDN).
- Using SQL Server Compact for ASP.NET Web Applications (MSDN).
- Microsoft SQL Server: Database Product Samples. Sample AdventureWorks databases.
- Installing Sample Databases. In addition to the methods shown here, you can also download one of the

sample .mdf files to the App_Data folder of a web project, convert the database to LocalDB, and create a LocalDB connection string. For information about how to do that, see How to: Upgrade to LocalDB.

See also the following sections on working with SQL Server Express and LocalDB, and choosing between SQL Server and SQL Database.

Working with SQL Server Express LocalDB Databases

- SQL Server Express 2012 LocalDB (MSDN). The official MSDN introduction to LocalDB.
- SQL Server Connection Strings for ASP.NET Web Applications (MSDN).
- How to: Upgrade to LocalDB (MSDN). How to migrate an .mdf file from an earlier version of SQL Server Express to LocalDB. You also have to go through this process if you download one of the SQL Server 2012 sample databases.
- Introducing LocalDB, an improved SQL Express (SQL Server Express blog). Has more background on why LocalDB was created than is included in MSDN.
- LocalDB: Where is My Database? (SQL Server Express blog). Information about where LocalDB database files are created.
- Using LocalDB with Full IIS, Part 1: User Profile (SQL Server Express blog). LocalDB is not designed to work with IIS. This series of blog posts explains the issues and some workarounds.

Working with SQL Server Express Databases

- SQL Server Connection Strings for ASP.NET Web Applications (MSDN). If you use the AttachDBFileName connection string setting with SQL Server Express, see especially the User Instance section of this page.
- How to take ownership of your local SQL Server Express 2008 (SQL Server Express blog). A common problem is not being able to work with SQL Server Express databases because you're not an administrator on the SQL Server Express instance. By default, only the person who installed SQL Server Express is an administrator. This blog explains how to make yourself a SQL Server Express administrator if you're an administrator on the computer.
- Can my ASP.NET web application use a SQL Server Express database in production? (MSDN).

Working with Windows Azure SQL Database

- Deploy a Secure ASP.NET MVC app with Membership, OAuth, and SQL Database to a Windows Azure Web Site (Microsoft Azure site).
- SQL Databases (Microsoft Azure site). Getting started tutorials and how-to guides.
- Windows Azure SQL Database (MSDN). The top-level node of the table of contents for SQL Database in MSDN.
- Windows Azure SQL Database TechNet Wiki Articles Index (Microsoft TechNet site).
- Transient Fault Handling Application Block. A framework that enables you to handle transient network faults and connection errors that result from throttling. Available in a NuGet package: Enterprise Library 5.0 - Transient Fault Handling Application Block.
- Getting Started with SQL Database and Entity Framework (MSDN).
- Windows Azure Training Kit (Microsoft Download Center). Includes hands-on labs for SQL Database.
- Windows Azure SQL Database Community Forum.
- Moving to Windows Azure SQL Database (MSDN). One chapter of a comprehensive end-to-end scenario by the Microsoft Patterns and Practices team. Covers why you might want to migrate and how to migrate from SQL Server to SQL Database.
- Migrating SQL Server Databases to Windows Azure SQL Database (MSDN).
- SQL Database Migration Wizard. An open source tool for migrating databases to and from SQL Database.

Choosing between SQL Server and Windows Azure SQL Database

- Compare SQL Server with Windows Azure SQL Database (Microsoft TechNet site).
- Data Migration to Windows Azure SQL Database: Tools and Techniques (MSDN). Includes sections that

compare SQL Server to SQL Database and provide guidance on when to migrate from SQL Server to SQL Database.

- Windows Azure SQL Database Delivery Guide (Microsoft TechNet site).
- SQL Server Feature Limitations (Windows Azure SQL Database) (MSDN).
- Windows Azure Table Storage and Windows Azure SQL Database - Compared and Contrasted (MSDN). For an application that you deploy to Windows Azure, Windows Azure Table storage might be an alternative to Windows Azure SQL Database. This topic helps you decide between these alternatives.
- Windows Azure SQL Database (MSDN).
- Guidelines and Limitations (Windows Azure SQL Database)

Working with NoSQL Database Management Systems

- Windows Azure Data Services (Microsoft Azure site). See the Table Service feature guide and the **Big Data** section of the page.
- ASP.NET Multi-Tier Application Using Storage Tables, Queues, and Blobs (Microsoft Azure site). End-to-end tutorial with downloadable sample application that uses Windows Azure storage NoSQL tables.

Using LINQ Queries in ASP.NET Applications

- ASP.NET Data Access Options (MSDN). Includes an introduction to LINQ.
- LINQ Training Videos (Joe Stagner's blog).
- ASP.NET Forum thread with links to dynamic LINQ resources.

Using Dynamic Data Scaffolding

- Dynamic Data Project Templates (MSDN). Guidance on when to use Dynamic Data projects.
- ASP.NET Dynamic Data (MSDN).

Securing Data Access

- Securing Data Access in ASP.NET (MSDN).
- Security Considerations (Entity Framework) (MSDN).
- How To: Secure Connection Strings when Using Data Source Controls (MSDN).

Optimizing Data Access Performance

- ASP.NET Performance Overview (MSDN).
- ASP.NET Caching (MSDN).
- Improving ASP.NET Performance (MSDN). There is a "Retired Content" warning at the top of this page, but most of the information is still relevant and there is no comparable updated resource.
- Improving SQL Server Performance (MSDN). Same comment as the previous link.

See also Optimizing Entity Framework performance earlier in this topic.

Deploying a Database

- ASP.NET Web Deployment - Recommended Resources (MSDN).

Accessing Data through a Web Service

- Accessing Data through a Web Service (MSDN). Guidance on when to use Web API versus WCF.
- Getting Started with ASP.NET Web API.

- WCF Data Services (MSDN).

Additional Resources

- ASP.NET Data Access FAQ (MSDN).
- ASP.NET Web Forms Tutorials - Data. Most of these tutorials are relatively old; make sure you read ASP.NET Data Access Options and Data Storage Options (Building Real-World Cloud Apps with Windows Azure) first so that you don't get too far into a data access method that isn't right for your scenario.
- ASP.NET MVC Content Map.
- ASP.NET Web Pages Tutorials - Data.
- Accessing Data in Visual Studio (MSDN). Provides a list of links similar to this content map but with a focus on Visual Studio rather than ASP.NET.

ASP.NET Web Deployment - Recommended Resources

2/20/2020 • 11 minutes to read • Edit Online

This topic provides links to documentation resources about how to deploy (publish) ASP.NET web applications to IIS by using Visual Studio 2010, Visual Web Developer 2010, and later versions.

If you know a great blog post, stackoverflow thread, or any other link that would be useful, send us an email with the link.

> **NOTE**
> Many of these resources describe deployment features that are available only if you install a recent release of the Visual Studio Web Publish Update. Some of the features are available only in Visual Studio 2012 or Visual Studio 2013.

This topic contains the following sections:

- Understanding deployment options for web projects
- Finding hosting providers for an ASP.NET application
- Deploying a web application from Visual Studio
- Deploying a web application by creating and installing a web deployment package
- Deploying a web application using a continuous integration (CI) process
- Using Web.config transformations to change settings in the destination Web.config file or app.config file during deployment
- Using Web Deploy parameters to change settings in the destination web application during deployment
- Making sure an application is off-line during deployment
- Deploying a database or changes to a database as part of web application deployment
- Deploying a database separately from web application deployment
- Deploying a web application that uses ASP.NET application services such as membership and profiling
- Precompiling for deployment
- Deploying an intranet web application
- Automating common deployment tasks that are not automated out of the box
- Configuring web servers so that developers can deploy web applications to them using Web Deploy
- Configuring servers for a hosting provider
- Troubleshooting deployment problems
- Getting help with a specific deployment question
- Additional Resources

Understanding deployment options for web projects

- Web Deployment Overview for Visual Studio and ASP.NET (MSDN).
- How to Deploy a Windows Azure Web Site. Explains options and links to resources for deploying web projects to Windows Azure Web Sites, including continuous delivery (automated from source control) as well as using Visual Studio.
- Visual Studio 2012 Web Publishing Improvements (Video by Scott Hanselman).

- Overview Post for Web Deployment in VS 2010 (Vishal Joshi's blog). An older blog post but some of the Visual Studio 2010 resources it links to have information that is still relevant for Visual Studio 2012.

Finding hosting providers for an ASP.NET application

- ASP.NET Hosting

Deploying a web application from Visual Studio

- How to Deploy a Windows Azure Web Site. Explains options and provides links to resources for deploying web projects to Windows Azure Web Sites. Includes a section about deploying from Visual Studio.
- ASP.NET Web Deployment using Visual Studio. 12-part tutorial series, shows how to deploy web applications with SQL Server databases. For database deployment uses both the dbDacFx provider and Entity Framework Code First Migrations. Also includes information about Web.config file transformations, deploying individual files, command-line deployment, and how to customize the Visual Studio web publish pipeline by editing .pubxml files. Applies to all ASP.NET web projects, including Web Forms, MVC, and Web API.)
- How to: Deploy a Web Project Using One-Click Publish in Visual Studio (Reference information for the Visual Studio Web Publish wizard.)
- Deploying an ASP.NET Web Application with SQL Server Compact using Visual Studio. This is an earlier version of **ASP.NET Web Deployment using Visual Studio** listed at the top of this section. Mainly useful now for information about how to deploy SQL Server Compact databases and how to migrate from SQL Server Compact to a full edition of SQL Server.
- .NET Multi-Tier Application Using Storage Tables, Queues, and Blobs (Microsoft Azure site). 5-part tutorial series, shows how to create an MVC project and deploy it to a Windows Azure Cloud Service.

Deploying a web application by creating and installing a web deployment package

- How to: Create a Web Deployment Package in Visual Studio (MSDN).
- How to: Install a Deployment Package Using the deploy.cmd File Created by Visual Studio (MSDN).
- Using a Web Deploy package to deploy to IIS on the dev box and to a third party host (Sayed Hashimi's blog). How to use IIS Manager to install a deployment package in IIS on the local computer and at a hosting company that supports IIS Manager for Remote Administration.
- Building a Web Deploy Package From Visual Studio 2010 (IIS.NET web site). Includes instructions for command-line package creation and installation.
- Package Once Publish Anywhere (Sayed Hashimi's blog). Introduces a NuGet package that automates the process of transforming the Web.config file for multiple destination environments, so that you can deploy one package to multiple servers. See also the PackageWeb video by Sayed Hashimi.

See also the following section.

Deploying a web application using a continuous integration (CI) process

- Continuous Integration and Continuous Delivery (Building Real-World Cloud Apps with Windows Azure). E-book chapter that introduces continuous integration and continuous delivery.
- How to Deploy a Windows Azure Web Site. Explains options and links to resources for deploying web projects to Windows Azure Web Sites. Includes a section about automating deployment from source control.
- Deploying Web Applications in Enterprise Scenarios. 40-part tutorial series, shows how to automate deployment in a CI process using Visual Studio 2010 and Team Foundation Server 2010.
- Inside the Microsoft Build Engine: Using MSBuild and Team Foundation Build, by Sayed Hashimi and William

Bartholomew. This is a book, not a web resource, but it is an essential guide for learning how to configure MSBuild for continuous integration scenarios.

- MSBuild Extension Pack. Includes deployment tasks.
- Team Foundation Build Customization Guide. Documentation by ALM Rangers on setting up Team Foundation Server covers web deployment and includes tutorials and videos.
- SlowCheetah XML transforms from a CI server (Sayed Hashimi's blog). Explains how to use SlowCheetah, A Visual Studio add-in for transforming app.config and other XML files.

See also Making sure an application is off-line during deployment later in this page.

Using Web.config transformations to change settings in the destination Web.config file or app.config file during deployment

- Web.config File Transformations.
- Web.config Transformation Syntax for Web Project Deployment Using Visual Studio (MSDN).
- Web Tools 2012.2 - web.config transforms (YouTube video by Sayed Hashimi). Shows how to set up and preview Web.config transforms.
- How do I disable Web.config transformation? (MSDN).
- When should I use Web Deploy parameters instead of Web.config transformations? (MSDN).
- XDT (XML Document Transform) released on codeplex.com (.NET Web Development and Tools blog). Announces availability of the source code for the Web.config file transformation engine and lists some tools that use it.
- Windows Azure Web Sites: How Application Strings and Connection Strings Work (Microsoft Azure blog). An alternative to Web.config transforms if your destination environment is Windows Azure Web Sites and you want to transform `appSettings` or `connectionStrings`.

Using Web Deploy parameters to change settings in the destination web application during deployment

- How to: Use Web Deploy Parameters in a Web Deployment Package (MSDN).
- MSDeploy: How to update app settings on publish based on the publish profile (Sayed Hashimi's blog). Shows how to integrate Web deploy parameters into Visual Studio publish profiles.
- Web Deploy Parameterization (IIS.NET web site).
- Web Deploy Parameterization in Action (Vishal Joshi's blog).
- Web Deploy Parameterization vs. Web.config Transformation (Vishal Joshi's blog).
- Windows Azure Web Sites: How Application Strings and Connection Strings Work (Microsoft Azure blog). An alternative to Web deploy parameters if your destination environment is Windows Azure Web Sites and you want to parameterize `appSettings` or `connectionStrings`.

Making sure an application is off-line during deployment

- ASP.NET Web Deployment using Visual Studio: Deploying a Code Update. See the section **Take the application offline during deployment.**
- Taking an Application Offline before Publishing (IIS.net site). Explains a feature built into Web Deploy 3.0 that automates handling of an app_offline.htm file. This feature does not work with custom app_offline.htm files.
- How to take your web app offline during publishing (Sayed Hashimi's blog). How to automate the process of using a custom app_offline.htm file.
- Web publishing updates for app offline and usechecksum (Microsoft Web Development blog). Another option for automating use of app_offline.htm file.
- Web Deploy 3.5 RTW (IIS.net site). New feature in Web Deploy 3.5 for custom app_offline.htm files.

Deploying a database or changes to a database as part of web application deployment

- Configuring Database Deployment in Visual Studio (MSDN). Overview of options for deploying a database with a web project.
- ASP.NET Web Deployment using Visual Studio. 12-part tutorial series, shows database deployment by using dbDacFx provider and Entity Framework Code First Migrations.
- How to: Deploy a Web Project Using One-Click Publish in Visual Studio (MSDN).
- Deploy a Secure ASP.NET MVC 5 app with Membership, OAuth, and SQL Database to a Windows Azure Web Site. A long tutorial that builds and deploys an application that uses a single SQL Server database both for membership and application data.
- Deploying an ASP.NET Web Application with SQL Server Compact using Visual Studio. 12-part tutorial series, shows how to deploy SQL Server Compact databases and how to migrate from SQL Server Compact to a full edition of SQL Server.

See also Deploying a web application by creating and installing a web deployment package and Deploying a web application using a continuous integration (CI) process earlier in this page.

Deploying a database separately from web application deployment

- SQL Server Data Tools (MSDN).
- Including Data in a SQL Server Database Project (SQL Server Data Tools team blog). How to deploy both schema and data when deploying a database.
- How to Deploy a Database to Windows Azure (Microsoft Azure site)
- Migrating Databases to Windows Azure SQL Database (formerly SQL Azure) (MSDN).
- Migrating a Database to SQL Azure using SSDT (SQL Server Data Tools team blog).
- Migrating Data-Centric Applications to Windows Azure (MSDN).
- Migrating SQL Server Databases to Windows Azure SQL Database (MSDN).

Deploying a web application that uses ASP.NET application services such as membership and profiling

- Deploy a Secure ASP.NET MVC 5 app with Membership, OAuth, and SQL Database to a Windows Azure Web Site. A long tutorial that builds and deploys an application that uses a single SQL Server database both for membership and application data.
- ASP.NET Identity. Resources for ASP.NET Identity.
- ASP.NET Web Deployment using Visual Studio. 12-part tutorial series, shows how to deploy an ASP.NET membership database.
- Configuring a Website that Uses Application Services. For web site projects but is also relevant for web application projects.
- Users and Roles On The Production Website. For web site projects but is also relevant for web application projects.

Precompiling for deployment

- ASP.NET Web Application Project Precompilation Overview (MSDN).
- Package/Publish Web Tab, Project Properties (MSDN).
- Advanced Precompile Settings Dialog Box (MSDN).

Deploying an intranet web application

- Use the On-Premises Organizational Authentication Option (ADFS) With ASP.NET in Visual Studio 2013 (Blog by Vittorio Bertocci.).
- How to Create an Intranet Site Using ASP.NET MVC (MSDN). Older walkthrough writen for Visual Studio 2010, does not reflect major changes in intranet project templates introduced in Visual Studio 2013.

Automating common deployment tasks that are not automated out of the box

- ASP.NET Web Deployment using Visual Studio: Deploying Extra Files.
- Setting Folder Permissions on Web Publish (Sayed Hashimi's blog).
- How to extend the targets file to include registry settings for a web project package (Web Development Tools blog).
- Extending XML (Web.config) transformation (Sayed Hashimi's blog). Shows how to create custom XDT transforms.
- Web Deployment Tool (MSDeploy) Custom Provider Take 1 (Sayed Hashimi's blog). Shows how to create a Web Deploy custom provider.
- How to package and deploy COM components (Web Development Tools blog).
- How to package .NET assemblies (Web Development Tools blog). How to deploy assemblies to the GAC.
- Script Out Everything - Initialize Your Windows Azure VM for Your Web Server with IIS, Web Deploy and Other Stuff (Tugberk Ugurlu's blog).

Configuring web servers so that developers can deploy web applications to them using Web Deploy

- Installing and Configuring Web Deploy for Administrator and non-administrator Deployments (IIS.net site).

Configuring servers for a hosting provider

- Microsoft ASP.NET 4 Hosting Deployment Guide (Microsoft Download Center).
- Generate a Profile XML File (IIS.net site).

Troubleshooting deployment problems

- Troubleshooting Windows Azure Web Sites in Visual Studio (Microsoft Azure site).
- ASP.NET Web Deployment using Visual Studio: Troubleshooting.
- Troubleshooting Common Problems With Web Deploy.
- Web Deploy Error Codes (IIS.net site).
- Web Deployment FAQ for Visual Studio and ASP.NET (MSDN).
- Core Differences Between IIS and the ASP.NET Development Server.
- Common Configuration Differences Between Development and Production.
- Hosting ASP.NET Applications in Medium Trust (4 Guys from Rolla site).

Getting help with a specific deployment question

- [ASP.NET Configuration and Deployment forum](https://forums.asp.net/26.aspx/1?Configuration and Deployment).
- StackOverflow.com.

Additional Resources

This section provides links to additional resources that are useful for learning more about how to use Visual Studio and IIS deployment tools.

The following blogs frequently contain information about Visual Studio web deployment:

- Web Development Tools at Microsoft blog.
- Sayed Hashimi's blog.

The following resources provide documentation about Web Deploy, the IIS framework that Visual Studio uses to perform web application project deployment tasks. You can ask questions about Web Deploy in the Web Deployment Tool forum on the IIS.net web site.

- Introduction to Web Deploy.
- Installing and Configuring Web Deploy.
- PowerShell Scripts for Automating Web Deploy Setup.
- Web Deployment Tool. Top-level table of contents node for Web Deploy documentation on the TechNet site. Includes useful reference information but most of the TechNet pages have not been updated for years.
- Microsoft.Web.Deployment Namespace. API documentation, has not been updated since version 1.0.
- The Microsoft Web Deployment Team blog.
- Publish tab in IIS.net web site.

ASP.NET and Web Tools 2012.2 Release Notes

2/20/2020 • 11 minutes to read • Edit Online

This document describes the release of ASP.NET and Web Tools 2012.2. It is an update to Visual Studio Web Tooling and ASP.NET.

- Installation Notes
- Documentation
- Support
- Software Requirements
- New Features in ASP.NET and Web Tools 2012.2
  - Tooling
  - Web Publishing
  - ASP.NET MVC Templates
  - ASP.NET Web API
  - ASP.NET SignalR
  - ASP.NET Friendly URLs
- Known Issues and Breaking Changes

Installation Notes

ASP.NET and Web Tools 2012.2 for Visual Studio 2012 can be installed using Web Platform installer. This is an update to Visual Studio 2012 or Visual Studio Express 2012 for Web, which is required. If you do not have Visual Studio installed, Visual Studio Express 2012 for Web will be installed.

You can also install ASP.NET and Web Tools 2012.2 manually. You must have Visual Studio 2012 or Visual Studio Express 2012 for Web installed. Then use the following instructions:

1. Download ASP.NET and Web Frameworks 2012.2 installer from Download Center.
2. When prompted click Run. You can also save the file to run it later.
3. Verify the version of Visual Studio you will update. You can do this by launching the Visual Studio you wish to update. Then click the Help menu item.

4. If you see the menu item "About Microsoft Visual Studio 2012 for Web" then download Web Developer Tools 2012.2 - Visual Studio Express 2012 for Web. Otherwise download Web Developer Tools 2012.2 - Visual Studio 2012.
5. When prompted click Run. You can also save the file to run it later.

> **NOTE**
> ASP.NET and Web Tools 2012.2 release does not include SQL Server Data Tools. SQL Server and Windows Azure SQL Databases provides a richer set of database tooling including offline project-backed development, schema comparison and enhanced database deployment capabilities. For more information or to install SQL Server Data Tools visit https://go.microsoft.com/fwlink/?LinkID=237127.

Documentation

Tutorials and other information about ASP.NET and Web Tools 2012.2 are available from ASP.NET web site (https://www.asp.net).

Support

ASP.NET and Web Tools 2012.2 is officially released and supported. You can use your normal support channel. You can also post questions to the ASP.NET forums (https://forums.asp.net/), where members of the ASP.NET community are frequently able to provide informal support.

Software Requirements

The ASP.NET and Web Tools 2012.2 requires Visual Studio 2012 or Visual Studio Express 2012 for Web.

New Features in ASP.NET and Web Tools 2012.2

This section describes features that have been introduced in the ASP.NET and Web Tools 2012.2 release.

Tooling

- Page Inspector
  - Support JavaScript selection mapping allowing Page Inspector to map items that were dynamically added to the page back to the corresponding JavaScript code.
  - The ability to see CSS updates in real-time.
  - For more information, read CSS Auto-Sync and JavaScript Selection Mapping in Page Inspector.
- Editor

  - Support syntax highlighting for CoffeeScript, Mustache, Handlebars, and JsRender.
  - The HTML editor provides Intellisense for Knockout bindings.
  - LESS editing and compiler support to enable building dynamic CSS using LESS.
  - Paste JSON as a .NET class. Using this Special Paste command to paste JSON into a C# or VB.NET code file, and Visual Studio will automatically generate .NET classes inferred from the JSON.
- Mobile Emulator support adds extensibility hooks so that third-party emulators can be installed as a VSIX. The installed emulators will show up in the F5 dropdown, so that developers can preview their websites on a variety of mobile devices. Read more about this feature in Scott Hanselman's blog entry on the new BrowserStack integration with Visual Studio.

Web Publishing

- Web site projects now have the same publishing experience as Web Application projects including publishing to Windows Azure Web Sites.
- Selective publish – for one or more files you can perform the following actions (after publishing to a Web Deploy endpoint):
  - Publish selected files.
  - See the difference between a local file and a remote file.
  - Update the local file with the remote file or update the remote file with the local file.

ASP.NET MVC Templates

- The new Facebook Application template makes writing Facebook Canvas applications easy. In a few simple steps, you can create a Facebook application that gets data from a logged in user and integrates with their friends. The template includes a new library to take care of all the plumbing involved in building a Facebook app, including authentication, permissions, accessing Facebook data and more. For more information on using the Facebook Application template see https://go.microsoft.com/fwlink/?LinkID=269921.
- A new Single Page Application MVC template allows developers to build interactive client-side web apps using HTML 5, CSS 3, and the popular Knockout and jQuery JavaScript libraries, on top of ASP.NET Web API. The template includes a "todo" list application that demonstrates common practices for building a JavaScript HTML5 application that uses a RESTful server API. You can read more at https://www.asp.net/single-page-application.
- You can now create a VSIX that adds new templates to the ASP.NET MVC New Project dialog. Learn how here: https://go.microsoft.com/fwlink/?LinkId=275019
- FixedDisplayModes package – MVC project templates have been updated to include the new 'FixedDisplayModes' NuGet package, which contains a workaround for a bug in MVC 4. For more information on the fix contained in the package, refer to this blog post (https://blogs.msdn.com/b/rickandy/archive/2012/09/17/asp-net-mvc-4-mobile-caching-bug-fixed.aspx) from the MVC team.

ASP.NET Web API

ASP.NET Web API has been enhanced with several new features:

- ASP.NET Web API OData
- ASP.NET Web API Tracing
- ASP.NET Web API Help Page

ASP.NET Web API OData

ASP.NET Web API OData gives you the flexibility you need to build OData endpoints with rich business logic over any data source. With ASP.NET Web API OData you control the amount of OData semantics that you want to expose. ASP.NET Web API OData is included with the ASP.NET MVC 4 project templates and is also available from NuGet (http://www.nuget.org/packages/microsoft.aspnet.webapi.odata).

ASP.NET Web API OData currently supports the following features:

- Enable OData query semantics by applying the [Queryable] attribute.
- Easily validate OData queries and restrict the set of supported query options, operators and functions.
- Parameter bind to ODataQueryOptions directly to get an abstract syntax tree representation of the query that can then be validated and applied to an IQueryable or IEnumerable.
- Enable service-driven paging and next page link generation by specifying result limits on [Queryable] attribute.
- Request an inlined count of the total number of matching resources using $inlinecount.
- Control null propagation.
- Any/All operators in $filter.
- Infer an entity data model by convention or explicitly customize a model in a manner similar to Entity Framework Code-First.
- Expose entity sets by deriving from EntitySetController.
- Simple, customizable conventions for exposing navigation properties, manipulating links and implementing OData actions.
- Simplified routing using the MapODataRoute extension method.
- Support for versioning by exposing multiple EDM models.
- Expose service document and $metadata so you can generate clients (.NET, Windows Phone, Windows Store, etc.) for your Web API.
- Support for the OData Atom, JSON, and JSON verbose formats.
- Create, update, partially update (PATCH) and delete entities.
- Query and manipulate relationships between entities.
- Create relationship links that wire up to your routes.
- Complex types.
- Entity Type Inheritance.
- Collection properties.
- Enums.
- OData actions.
- Built upon the same foundation as WCF Data Services, namely ODataLib (http://www.nuget.org/packages/microsoft.data.odata).

For more information on ASP.NET Web API OData see https://go.microsoft.com/fwlink/?LinkId=271141.

ASP.NET Web API Tracing

ASP.NET Web API Tracing integrates tracing data from your web APIs with .NET Tracing. It is now enabled by default in the Web API project template. Tracing data for your web APIs is sent to the Output window and is made available through IntelliTrace. ASP.NET Web API Tracing enables you to trace information about your Web API when hosted on Windows Azure through integration with Windows Azure Diagnostics. You can also install and enable ASP.NET Web API Tracing in any application using the ASP.NET Web API Tracing NuGet package (http://www.nuget.org/packages/microsoft.aspnet.webapi.tracing).

For more information on configuring and using ASP.NET Web API Tracing see https://go.microsoft.com/fwlink/?LinkID=269874.

ASP.NET Web API Help Page

The ASP.NET Web API Help Page is now included by default in the Web API project template. The ASP.NET Web API Help Page automatically generates documentation for web APIs including the HTTP endpoints, the supported HTTP methods, parameters and example request and response message payloads. Documentation is automatically pulled from comments in your code. You can also add the ASP.NET Web API Help Page to any application using the ASP.NET Web API Help Page NuGet package (http://www.nuget.org/packages/microsoft.aspnet.webapi.helppage).

For more information on setting up and customizing the ASP.NET Web API Help Page see https://go.microsoft.com/fwlink/?LinkId=271140.

ASP.NET SignalR

ASP.NET SignalR makes it simple to add real-time web capabilities to your ASP.NET application, using WebSockets if available and automatically falling back to other techniques when it isn't.

For more information on using ASP.NET SignalR see https://go.microsoft.com/fwlink/?LinkId=271271.

ASP.NET Friendly URLs

ASP.NET FriendlyURLs makes it very easy for web forms developers to generate cleaner looking URLs(without the .aspx extension). It requires little to no configuration and can be used with existing ASP.NET v4.0 applications. The FriendlyURLs feature also makes it easier for developers to add mobile support to their applications, by supporting switching between desktop and mobile views.

For more information on installing and using ASP.NET Friendly URLs see http://www.hanselman.com/blog/IntroducingASPNETFriendlyUrlsCleanerURLsEasierRoutingAndMobileViewsForASPNETWebForms.aspx.

Known Issues and Breaking Changes

This section describes known issues and breaking changes that are in the ASP.NET and Web Tools 2012.2 release.

Installation Issues

Out of order installs of Visual Studio 2012

Installing an additional SKU of Visual Studio 2012 after installing the ASP.NET and Web Tools 2012.2 will require a repair operation. Consider the following sequence:

1. Install Visual Studio 2012 Express for Web
2. Install ASP.NET and Web Tools 2012.2
3. Install Visual Studio 2012 Professional, Premium or Ultimate

Step 2 would only result in installing updates for Express for Web. To ensure that the additional SKU installed during step 3 contains the update you will need to repair the ASP.NET and Web Tools 2012.2 to install the updates for the last SKU installed. This also applies if the SKUs in Step 1 and 3 are reversed.

Installing Microsoft ASP.NET and Web Tools 2012.2 when Visual Studio is open

If VS is open during installation of Microsoft ASP.NET and Web Tools 2012.2, Visual Studio might end up in a bad state. It is recommended that users close all instances of Visual Studio before proceeding with install.

Canceling ASP.NET and Web Tools 2012.2 setup in the middle of installation

Canceling ASP.NET and Web Tools 2012.2 setup in the middle of installation will leave Visual Studio in a bad state. To address this problem follow these steps:

- Go to Add Remove Programs
- Uninstall Microsoft ASP.NET and Web Tools 2012.2, if present.
- Reinstall Microsoft ASP.NET and Web Tools 2012.2

After uninstalling ASP.NET and Web Tools 2012.2 the ASP.NET MVC 4 templates and Razor v2 Web Site templates are missing

Uninstalling ASP.NET and Web Tools 2012.2 will also uninstall all of ASP.NET MVC 4 and Razor v2 Web Site templates from Visual Studio 2012.

The workaround is to repair your Visual Studio 2012 installation to reinstall ASP.NET MVC 4 and Razor v2 Web Site templates.

Tooling Issues

NuGet error reported during project creation

After installing ASP.NET and Web Tools 2012.2 you may see the following error when creating an MVC 4 project

The ASP.NET and Web Tools 2012.2 ships NuGet 2.1 and will upgrade the extension in Visual Studio 2012. In some cases, the VSIX installer will fail to correctly update the VSIX. The following steps will allow you to address this problem:

1. Start Visual Studio 2012 as an Administrator
2. Go to Tools->Extensions and Updates and uninstall NuGet.
3. Close Visual Studio
4. Navigate to the ASP.NET and Web Tools 2012.2 installation folder:
   a. For Visual Studio 2012: **Program Files\Microsoft ASP.NET\ASP.NET Web Stack\Visual Studio 2012**
   b. For Visual Studio 2012 Express for Web: **Program Files\Microsoft ASP.NET\ASP.NET Web Stack\Visual Studio Express 2012 for Web**
5. Double click on the NuGet.Tools.vsix to reinstall NuGet

Web API Issues

Parsing issues in $filter and DateTime literals

The OData URI parser fails to parse partial datetime literals properly. For example, $filter=start eq datetime'2012-12-31T12:00' fails to parse properly. A workaround is to use the full literal, $filter=start eq datetime'2012-12-31T12:00:00'.

OData doesn't support case-insensitive property names.

OData doesn't support case-insensitive property names in OData queries and odata path. See workitems:

- http://aspnetwebstack.codeplex.com/workitem/366
- http://aspnetwebstack.codeplex.com/workitem/704

If users have different casing on javascript client side and server side, they probably will encounter this issue. This issue is by design in odata protocol. However, many users reports this issue. To work around it, users have to correct their cases in URL.

Default OData routing conventions doesn't support POST/PUT on navigation property.

Default OData routing conventions doesn't support POST/PUT on navigation property. See workitem http://aspnetwebstack.codeplex.com/workitem/366. We are missing this commonly used convention in default conventions.

To work around it, users need to extend new routing convention to support it.

Facebook Template Issues

Facebook Application template only works using .NET 4.5

You must select .NET 4.5 in the framework dropdown list in the New Project dialog to see the Facebook Application template in ASP.NET MVC 4.

Real-time Update Controller

The Facebook Application template allows user easily create a Web API Controller to handle real-time updates from

Facebook. If your development machine is behind NAT, your Controller may not work without further network configuration. See here for details: http://facebook.stackoverflow.com/questions/5259467/can-a-computer-behind-a-nat-router-receive-realtime-updates-from-facebook

Query string values conflict with Facebook OAuth parameters

The following fields conflict with Facebook OAuth dialog's call back URL. Do not add your own query string values with the following names: code, error, error_description, error_reason.

Using Page Inspector with Facebook Template

You can't use the Page Inspector feature in Visual Studio 2012 while debugging your Facebook Application. The Page Inspector does not currently support iframes.

Single Page Application Template Issues

With JQuery 1.9/Knockout 2.2.1 update, when running default MVC SPA project, new todo item edit enter focus event is not handled properly.

With JQuery 1.9/Knockout 2.2.1 update, when running default MVC SPA project, new todo item edit enter no longer focus back to the new todo item edit box after entering the new todo item to the todo list.

To workaround reference http://knockoutjs.com/documentation/hasfocus-binding.html, and make similar fix to the following sample code:

File todo.model.js
function todolist(data), add following:
self.isSelected = ko.observable(false);

function todoList.prototype.addTodo, add the following blacked text:
self.isSelected(true);
self.newTodoTitle("");

File index.cshtml, add the following blacked text:
<form data-bind="submit: addTodo">
<input class="addTodo" type="text" data-bind="value: newTodoTitle, placeholder: 'Type here to add', blurOnEnter: true, **hasfocus: isSelected**, event: { blur: addTodo }" />
</form>

What's New in ASP.NET 4.5 and Visual Studio 2012

2/20/2020 • 45 minutes to read • Edit Online

This document describes new features and enhancements that are being introduced in ASP.NET 4.5. It also describes improvements being made for web development in Visual Studio 2012. This document was originally published on February 29, 2012.

- ASP.NET Core Runtime and Framework
  - Asynchronously Reading and Writing HTTP Requests and Responses
  - Improvements to HttpRequest handling
  - Asynchronously flushing a response
  - Support for *await* and *Task*-Based Asynchronous Modules and Handlers
  - Asynchronous HTTP modules
  - Asynchronous HTTP handlers
  - New ASP.NET Request Validation Features
  - Deferred ("lazy") request validation
  - Support for unvalidated requests
  - AntiXSS Library
  - Support for WebSockets Protocol
  - Bundling and Minification
  - Performance Improvements for Web Hosting
    - Key Performance Factors
    - Requirements for New Performance Features
    - Sharing Common Assemblies
    - Using multi-Core JIT compilation for faster startup
    - Tuning garbage collection to optimize for memory
    - Prefetching for web applications
- ASP.NET Web Forms
  - Strongly Typed Data Controls
  - Model Binding
    - Selecting data
    - Value providers
    - Filtering by values from a control
  - HTML Encoded Data-Binding Expressions
  - Unobtrusive Validation
  - HTML5 Updates

- ASP.NET MVC 4
- ASP.NET Web Pages 2
- Visual Studio 2012 Release Candidate
  - Project Sharing Between Visual Studio 2010 and Visual Studio 2012 Release Candidate (Project Compatibility)
  - Configuration Changes in ASP.NET 4.5 Website Templates
  - Native Support in IIS 7 for ASP.NET Routing
  - HTML Editor
    - Smart Tasks
    - WAI-ARIA support
    - New HTML5 snippets
    - Extract to user control
    - IntelliSense for code nuggets in attributes
    - Automatic renaming of matching tag when you rename an opening or closing tag
    - Event handler generation
    - Smart indent
    - Auto-reduce statement completion
  - JavaScript Editor
    - Code outlining
    - Brace matching
    - Go to Definition
    - ECMAScript5 support
    - DOM IntelliSense
    - VSDOC signature overloads
    - Implicit references
  - CSS Editor
    - Auto-reduce statement completion
    - Hierarchical indentation.
    - CSS hacks support
    - Vendor specific schemas (-moz-,-webkit)
    - Commenting and uncommenting support
    - Color picker

ASP.NET Core Runtime and Framework

Asynchronously Reading and Writing HTTP Requests and Responses

ASP.NET 4 introduced the ability to read an HTTP request entity as a stream using the *HttpRequest.GetBufferlessInputStream* method. This method provided streaming access to the request entity. However, it executed synchronously, which tied up a thread for the duration of a request.

ASP.NET 4.5 supports the ability to read streams asynchronously on an HTTP request entity, and the ability to flush asynchronously. ASP.NET 4.5 also gives you the ability to double-buffer an HTTP request entity, which provides easier integration with downstream HTTP handlers such as .aspx page handlers and ASP.NET MVC controllers.

Improvements to HttpRequest handling

The Stream reference returned by ASP.NET 4.5 from *HttpRequest.GetBufferlessInputStream* supports both synchronous and asynchronous read methods. The *Stream* object returned from *GetBufferlessInputStream* now implements both the BeginRead and EndRead methods. The asynchronous *Stream* methods let you asynchronously read the request entity in chunks, while ASP.NET releases the current thread between each iteration of an asynchronous read loop.

ASP.NET 4.5 has also added a companion method for reading the request entity in a buffered way: *HttpRequest.GetBufferedInputStream*. This new overload works like *GetBufferlessInputStream*, supporting both synchronous and asynchronous reads. However, as it reads, *GetBufferedInputStream* also copies the entity bytes into ASP.NET internal buffers so that downstream modules and handlers can still access the request entity. For example, if some upstream code in the pipeline has already read the request entity using *GetBufferedInputStream*, you can still use *HttpRequest.Form* or *HttpRequest.Files*. This lets you perform asynchronous processing on a request (for example, streaming a large file upload to a database), but still run .aspx pages and MVC ASP.NET controllers afterward.

Asynchronously flushing a response

Sending responses to an HTTP client can take considerable time when the client is far away or has a low-bandwidth connection. Normally ASP.NET buffers the response bytes as they are created by an application. ASP.NET then performs a single send operation of the accrued buffers at the very end of request processing.

If the buffered response is large (for example, streaming a large file to a client), you must periodically call *HttpResponse.Flush* to send buffered output to the client and keep memory usage under control. However, because *Flush* is a synchronous call, iteratively calling *Flush* still consumes a thread for the duration of potentially long-running requests.

ASP.NET 4.5 adds support for performing flushes asynchronously using the *BeginFlush* and *EndFlush* methods of the *HttpResponse* class. Using these methods, you can create asynchronous modules and asynchronous handlers that incrementally send data to a client without tying up operating-system threads. In between *BeginFlush* and *EndFlush* calls, ASP.NET releases the current thread. This substantially reduces the total number of active threads that are needed in order to support long-running HTTP downloads.

Support for *await* and *Task* - Based Asynchronous Modules and Handlers

The .NET Framework 4 introduced an asynchronous programming concept referred to as a *task*. Tasks are represented by the *Task* type and related types in the *System.Threading.Tasks* namespace. The .NET Framework 4.5 builds on this with compiler enhancements that make working with *Task* objects simple. In the .NET Framework 4.5, the compilers support two new keywords: *await* and *async*. The *await* keyword is syntactical shorthand for indicating that a piece of code should asynchronously wait on some other piece of code. The *async* keyword represents a hint that you can use to mark methods as task-based asynchronous methods.

The combination of *await*, *async*, and the *Task* object makes it much easier for you to write asynchronous code in .NET 4.5. ASP.NET 4.5 supports these simplifications with new APIs that let you write asynchronous HTTP modules and asynchronous HTTP handlers using the new compiler enhancements.

Asynchronous HTTP modules

Suppose that you want to perform asynchronous work within a method that returns a *Task* object. The following code example defines an asynchronous method that makes an asynchronous call to download the Microsoft home page. Notice the use of the *async* keyword in the method signature and the *await* call to *DownloadStringTaskAsync*.

```
private async Task
ScrapeHtmlPage(object caller, EventArgs e)
{
    WebClient wc = new WebClient();
    var result = await wc.DownloadStringTaskAsync("http://www.microsoft.com");
    // Do something with the result
}
```

That's all you have to write — the .NET Framework will automatically handle unwinding the call stack while waiting for the download to complete, as well as automatically restoring the call stack after the download is done.

Now suppose that you want to use this asynchronous method in an asynchronous ASP.NET HTTP module. ASP.NET 4.5 includes a helper method (*EventHandlerTaskAsyncHelper*) and a new delegate type (*TaskEventHandler*) that you can use to integrate task-based asynchronous methods with the older asynchronous programming model exposed by the ASP.NET HTTP pipeline. This example shows how:

```
public void Init(HttpApplication
context)
 {
   // Wrap the Task-based method so that it can be used with
   // the older async programming model.
   EventHandlerTaskAsyncHelper helper =
       new EventHandlerTaskAsyncHelper(ScrapeHtmlPage);

   // The helper object makes it easy to extract Begin/End methods out of
   // a method that returns a Task object. The ASP.NET pipeline calls the
   // Begin and End methods to start and complete calls on asynchronous
   // HTTP modules.
   context.AddOnPostAuthorizeRequestAsync(
       helper.BeginEventHandler, helper.EndEventHandler);
}
```

Asynchronous HTTP handlers

The traditional approach to writing asynchronous handlers in ASP.NET is to implement the *IHttpAsyncHandler* interface. ASP.NET 4.5 introduces the *HttpTaskAsyncHandler* asynchronous base type that you can derive from, which makes it much easier to write asynchronous handlers.

The *HttpTaskAsyncHandler* type is abstract and requires you to override the *ProcessRequestAsync* method. Internally ASP.NET takes care of integrating the return signature (a *Task* object) of *ProcessRequestAsync* with the older asynchronous programming model used by the ASP.NET pipeline.

The following example shows how you can use *Task* and *await* as part of the implementation of an asynchronous HTTP handler:

```
public class MyAsyncHandler : HttpTaskAsyncHandler
{
    // ...

    // ASP.NET automatically takes care of integrating the Task based override
    // with the ASP.NET pipeline.
    public override async Task ProcessRequestAsync(HttpContext context)
    {
        WebClient wc = new WebClient();
        var result = await
           wc.DownloadStringTaskAsync("http://www.microsoft.com");
        // Do something with the result
    }
}
```

New ASP.NET Request Validation Features

By default, ASP.NET performs request validation — it examines requests to look for markup or script in fields, headers, cookies, and so on. If any is detected, ASP.NET throws an exception. This acts as a first line of defense against potential cross-site scripting attacks.

ASP.NET 4.5 makes it easy to selectively read unvalidated request data. ASP.NET 4.5 also integrates the popular AntiXSS library, which was formerly an external library.

Developers have frequently asked for the ability to selectively turn off request validation for their applications. For example, if your application is forum software, you might want to allow users to submit HTML-formatted forum posts and comments, but still make sure that request validation is checking everything else.

ASP.NET 4.5 introduces two features that make it easy for you to selectively work with unvalidated input: deferred ("lazy") request validation and access to unvalidated request data.

Deferred ("lazy") request validation

In ASP.NET 4.5, by default all request data is subject to request validation. However, you can configure the application to defer request validation until you actually access request data. (This is sometimes referred to as lazy request validation, based on terms like lazy loading for certain data scenarios.) You can configure the application to use deferred validation in the Web.config file by setting the *requestValidationMode* attribute to 4.5 in the *httpRUntime* element, as in the following example:

```
<httpRuntime requestValidationMode="4.5" ... />
```

When request validation mode is set to 4.5, request validation is triggered only for a specific request value and only when your code accesses that value. For example, if your code gets the value of Request.Form["forum_post"], request validation is invoked only for that element in the form collection. None of the other elements in the *Form* collection are validated. In previous versions of ASP.NET, request validation was triggered for the entire request collection when any element in the collection was accessed. The new behavior makes it easier for different application components to look at different pieces of request data without triggering request validation on other pieces.

Support for unvalidated requests

Deferred request validation alone doesn't solve the problem of selectively bypassing request validation. The call to Request.Form["forum_post"] still triggers request validation for that specific request value. However, you might want to access this field without triggering validation because you want to allow markup in that field.

To allow this, ASP.NET 4.5 now supports unvalidated access to request data. ASP.NET 4.5 includes a new *Unvalidated* collection property in the *HttpRequest* class. This collection provides access to all of the common values of request data, like *Form*, *QueryString*, *Cookies*, and *Url*.

Using the forum example, to be able to read unvalidated request data, you first need to configure the application to

use the new request validation mode:

```
<httpRuntime requestValidationMode="4.5" ...
/>
```

You can then use the *HttpRequest.Unvalidated* property to read the unvalidated form value:

```
var s = context.Request.Unvalidated.Form["forum_post"];
```

WARNING

Security - *Use unvalidated request data with care!* ASP.NET 4.5 added the unvalidated request properties and collections to make it easier for you to access very specific unvalidated request data. However, you must still perform custom validation on the raw request data to ensure that dangerous text is not rendered to users.

AntiXSS Library

Due to the popularity of the Microsoft AntiXSS Library, ASP.NET 4.5 now incorporates core encoding routines from version 4.0 of that library.

The encoding routines are implemented by the *AntiXssEncoder* type in the new *System.Web.Security.AntiXss* namespace. You can use the *AntiXssEncoder* type directly by calling any of the static encoding methods that are implemented in the type. However, the easiest approach for using the new anti-XSS routines is to configure an ASP.NET application to use the *AntiXssEncoder* class by default. To do this, add the following attribute to the Web.config file:

```
<httpRuntime ...
  encoderType="System.Web.Security.AntiXss.AntiXssEncoder,System.Web, Version=4.0.0.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a" />
```

When the *encoderType* attribute is set to use the *AntiXssEncoder* type, all output encoding in ASP.NET automatically uses the new encoding routines.

These are the portions of the external AntiXSS library that have been incorporated into ASP.NET 4.5:

- *HtmlEncode*, *HtmlFormUrlEncode*, and *HtmlAttributeEncode*
- *XmlAttributeEncode* and *XmlEncode*
- *UrlEncode* and *UrlPathEncode* (new)
- *CssEncode*

Support for WebSockets Protocol

WebSockets protocol is a standards-based network protocol that defines how to establish secure, real-time bidirectional communications between a client and a server over HTTP. Microsoft has worked with both the IETF and W3C standards bodies to help define the protocol. The WebSockets protocol is supported by any client (not just browsers), with Microsoft investing substantial resources supporting WebSockets protocol on both client and mobile operating systems.

WebSockets protocol makes it much easier to create long-running data transfers between a client and a server. For example, writing a chat application is much easier because you can establish a true long-running connection between a client and a server. You do not have to resort to workarounds like periodic polling or HTTP long-polling to simulate the behavior of a socket.

ASP.NET 4.5 and IIS 8 include low-level WebSockets support, enabling ASP.NET developers to use managed APIs for asynchronously reading and writing both string and binary data on a WebSockets object. For ASP.NET 4.5, there is

a new *System.Web.WebSockets* namespace that contains types for working with WebSockets protocol.

A browser client establishes a WebSockets connection by creating a DOM *WebSocket* object that points to a URL in an ASP.NET application, as in the following example:

```
socket = new WebSocket("ws://contoso.com/MyWebSocketApplication.ashx");
```

You can create WebSockets endpoints in ASP.NET using any kind of module or handler. In the previous example, an .ashx file was used, because .ashx files are a quick way to create a handler.

According to the WebSockets protocol, an ASP.NET application accepts a client's WebSockets request by indicating that the request should be upgraded from an HTTP GET request to a WebSockets request. Here's an example:

```
HttpContext.Current.AcceptWebSocketRequest(// WebSocket delegate goes here)
```

The *AcceptWebSocketRequest* method accepts a function delegate because ASP.NET unwinds the current HTTP request and then transfers control to the function delegate. Conceptually this approach is similar to how you use *System.Threading.Thread*, where you define a thread-start delegate in which background work is performed.

After ASP.NET and the client have successfully completed a WebSockets handshake, ASP.NET calls your delegate and the WebSockets application starts running. The following code example shows a simple echo application that uses the built-in WebSockets support in ASP.NET:

```
public async Task MyWebSocket(AspNetWebSocketContext context)
{
    WebSocket socket = context.WebSocket;
    while (true)
    {
        ArraySegment<byte> buffer = new ArraySegment<byte>(new byte[1024]);

        // Asynchronously wait for a message to arrive from a client
        WebSocketReceiveResult result =
           await socket.ReceiveAsync(buffer, CancellationToken.None);

        // If the socket is still open, echo the message back to the client
        if (socket.State == WebSocketState.Open)
        {
           string userMessage = Encoding.UTF8.GetString(buffer.Array, 0,
               result.Count);
           userMessage = "You sent: " + userMessage + " at " +
               DateTime.Now.ToLongTimeString();
           buffer = new ArraySegment<byte>(Encoding.UTF8.GetBytes(userMessage));

           // Asynchronously send a message to the client
           await socket.SendAsync(buffer, WebSocketMessageType.Text,
               true, CancellationToken.None);
        }
        else { break; }
    }
}
```

The support in .NET 4.5 for the *await* keyword and asynchronous task-based operations is a natural fit for writing WebSockets applications. The code example shows that a WebSockets request runs completely asynchronously inside ASP.NET. The application waits asynchronously for a message to be sent from a client by calling *await socket.ReceiveAsync*. Similarly, you can send an asynchronous message to a client by calling *await socket.SendAsync*.

In the browser, an application receives WebSockets messages through an *onmessage* function. To send a message from a browser, you call the *send* method of the *WebSocket* DOM type, as shown in this example:

```
// Receive a string message from the server.
socket.onmessage = function(msg)
{
    document.getElementById("serverData").innerHTML = msg.data;
};
// Send a string message from the browser.
socket.send(document.getElementById("msgText"));
```

In the future, we might release updates to this functionality that abstract away some of the low-level coding that is required in this release for WebSockets applications.

Bundling and Minification

Bundling lets you combine individual JavaScript and CSS files into a bundle that can be treated like a single file. Minification condenses JavaScript and CSS files by removing whitespace and other characters that are not required. These features work with Web Forms, ASP.NET MVC, and Web Pages.

Bundles are created using the Bundle class or one of its child classes, ScriptBundle and StyleBundle. After configuring an instance of a bundle, the bundle is made available to incoming requests by simply adding it to a global BundleCollection instance. In the default templates, bundle configuration is performed in a BundleConfig file. This default configuration creates bundles for all of the core scripts and css files used by the templates.

Bundles are referenced from within views by using one of a couple possible helper methods. In order to support rendering different markup for a bundle when in debug vs. release mode, the ScriptBundle and StyleBundle classes have the helper method, Render. When in debug mode, Render will generate markup for each resource in the bundle. When in release mode, Render will generate a single markup element for the entire bundle. Toggling between debug and release mode can be accomplished by modifying the debug attribute of the compilation element in web.config as shown below:

```
<system.web>
 <compilation targetframework="4.5" debug="true" />
 ...</system.web>
```

Additionally, enabling or disabling optimization can be set directly via the BundleTable.EnableOptimizations property.

```
BundleTable.EnableOptimizations = true;
```

When files are bundled, they are first sorted alphabetically (the way they are displayed in **Solution Explorer**). They are then organized so that known libraries and their custom extensions (such as jQuery, MooTools, and Dojo) are loaded first. For example, the final order for the bundling of the Scripts folder as shown above will be:

1. jquery-1.6.2.js
2. jquery-ui.js
3. jquery.tools.js
4. a.js

CSS files are also sorted alphabetically and then reorganized so that reset.css and normalize.css come before any other file. The final sorting of the bundling of the Styles folder shown above will be this:

1. reset.css
2. content.css
3. forms.css
4. globals.css
5. menu.css

6. styles.css

Performance Improvements for Web Hosting

The .NET Framework 4.5 and Windows 8 introduce features that can help you achieve a significant performance boost for web-server workloads. This includes a reduction (up to 35%) in both startup time and in the memory footprint of web hosting sites that use ASP.NET.

Key performance factors

Ideally, all websites should be active and in memory to assure quick response to the next request, whenever it comes. Factors that can affect site responsiveness include:

- The time it takes for a site to restart after an app pool recycles. This is the time it takes to launch a web server process for the site when the site assemblies are no longer in memory. (The platform assemblies are still in memory, since they are used by other sites.) This situation is referred to as "cold site, warm framework startup" or just "cold site startup."
- How much memory the site occupies. Terms for this are "per-site memory consumption" or "unshared working set."

The new performance improvements focus on both of these factors.

Requirements for New Performance Features

The requirements for the new features can be broken down into these categories:

- Improvements that run on the .NET Framework 4.
- Improvements that require the .NET Framework 4.5 but can run on any version of Windows.
- Improvements that are available only with .NET Framework 4.5 running on Windows 8.

Performance increases with each level of improvement that you are able to enable.

Some of the .NET Framework 4.5 improvements take advantage of broader performance features that apply to other scenarios as well.

Sharing Common Assemblies

Requirement: .NET Framework 4 and Visual Studio 11 Developer Preview SDK

Different sites on a server often use the same helper assemblies (for example, assemblies from a starter kit or sample application). Each site has its own copy of these assemblies in its Bin directory. Even though the object code for the assemblies is identical, they're physically separate assemblies, so each assembly has to be read separately during cold site startup and kept separately in memory.

The new interning functionality solves this inefficiency and reduces both RAM requirements and load time. Interning lets Windows keep a single copy of each assembly in the file system, and individual assemblies in the site Bin folders are replaced with symbolic links to the single copy. If an individual site needs a distinct version of the assembly, the symbolic link is replaced by the new version of the assembly, and only that site is affected.

Sharing assemblies using symbolic links requires a new tool named aspnet_intern.exe, which lets you create and manage the store of interned assemblies. It is provided as a part of the Visual Studio 11 Developer Preview SDK. (However, it will work on a system that has only the .NET Framework 4 installed, assuming you have installed the latest update.)

To make sure all eligible assemblies have been interned, you run aspnet_intern.exe periodically (for example, once a week as a scheduled task). A typical use is as follows:

```
aspnet_intern -mode exec -sourcedir
"C:\Windows\Microsoft.NET\Framework\v4.0.30319\Temporary ASP.NET Files" -interndir C:\ASPNETCommonAssemblies
```

To see all options, run the tool with no arguments.

Using multi-Core JIT compilation for faster startup

Requirement: .NET Framework 4.5

For a cold site startup, not only do assemblies have to be read from disk, but the site must be JIT-compiled. For a complex site, this can add significant delays. A new general-purpose technique in the .NET Framework 4.5 reduces these delays by spreading JIT-compilation across available processor cores. It does this as much and as early as possible by using information gathered during previous launches of the site. This functionality implemented by the System.Runtime.ProfileOptimization.StartProfile method.

JIT-compiling using multiple cores is enabled by default in ASP.NET, so you do not need to do anything to take advantage of this feature. If you want to disable this feature, make the following setting in the Web.config file:

```
<configuration>
  <!-- ... -->
  <system.web>
<compilation profileGuidedOptimizations="None"  />
  <!-- ... -->
```

Tuning garbage collection to optimize for memory

Requirement: .NET Framework 4.5

Once a site is running, its use of the garbage-collector (GC) heap can be a significant factor in its memory consumption. Like any garbage collector, the .NET Framework GC makes tradeoffs between CPU time (frequency and significance of collections) and memory consumption (extra space that is used for new, freed, or free-able objects). For previous releases, we have provided guidance on how to configure the GC to achieve the right balance (for example, see ASP.NET 2.0/3.5 Shared Hosting Configuration).

For the .NET Framework 4.5, instead of multiple standalone settings, a workload-defined configuration setting is available that enables all of the previously recommended GC settings as well as new tuning that delivers additional performance for the per-site working set.

To enable GC memory tuning, add the following setting to the Windows\Microsoft.NET\Framework\v4.0.30319\aspnet.config file:

```
<configuration>
  <!-- ... -->
  <runtime>
<performanceScenario value="HighDensityWebHosting"  />
  <!-- ... -->
```

(If you're familiar with the previous guidance for changes to aspnet.config, note that this setting replaces the old settings — for example, there is no need to set gcServer, gcConcurrent, etc. You do not have to remove the old settings.)

Prefetching for web applications

Requirement: .NET Framework 4.5 running on Windows 8

For several releases, Windows has included a technology known as the prefetcher that reduces the disk-read cost of application startup. Because cold startup is a problem predominantly for client applications, this technology has not been included in Windows Server, which includes only components that are essential to a server. Prefetching is now available in the latest version of Windows Server, where it can optimize the launch of individual websites.

For Windows Server, the prefetcher is not enabled by default. To enable and configure the prefetcher for high-density web hosting, run the following set of commands at the command line:

```
sc config sysmain start=auto
reg add "HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory
Management\PrefetchParameters" /v EnablePrefetcher /t REG_DWORD /d 2 /f
reg add "HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Prefetcher" /v MaxPrefetchFiles /t
REG_DWORD /d 8192 /f
net start sysmain
```

Then, to integrate the prefetcher with ASP.NET applications, add the following to the Web.config file:

```
<configuration>
  <!-- ... -->
  <system.web>
<compilation enablePrefetchOptimization="true" />
  <!-- ... -->
```

ASP.NET Web Forms

Strongly Typed Data Controls

In ASP.NET 4.5, Web Forms includes some improvements for working with data. The first improvement is strongly typed data controls. For Web Forms controls in previous versions of ASP.NET, you display a data-bound value using *Eval* and a data-binding expression:

```
<ul>
<asp:Repeater runat="server" ID="customers">
       <ItemTemplate>
           <li>
               First Name: <%# Eval("FirstName")%><br />
               Last Name: <%# Eval("LastName")%><br />
           </li>
       </ItemTemplate>
</asp:Repeater>
</ul>
```

For two-way data binding, you use *Bind*:

```
<asp:FormView runat="server" ID="editCustomer">
<EditItemTemplate>
       <div>
           <asp:Label runat="server" AssociatedControlID="firstName">
               First Name:</asp:Label>
           <asp:TextBox ID="firstName" runat="server"
               Text='<%#Bind("FirstName") %>' />
       </div>
       <div>
           <asp:Label runat="server" AssociatedControlID="lastName">
               First Name:</asp:Label>
           <asp:TextBox ID="lastName" runat="server"
               Text='<%#
Bind("LastName") %>' />
       </div>
       <asp:Button runat="server" CommandName="Update"/>
</EditItemTemplate>
</asp:FormView>
```

At run time, these calls use reflection to read the value of the specified member and then display the result in the markup. This approach makes it easy to data bind against arbitrary, unshaped data.

However, data-binding expressions like this don't support features like IntelliSense for member names, navigation

(like Go To Definition), or compile-time checking for these names.

To address this issue, ASP.NET 4.5 adds the ability to declare the data type of the data that a control is bound to. You do this using the new *ItemType* property. When you set this property, two new typed variables are available in the scope of data-binding expressions: *Item* and *BindItem*. Because the variables are strongly typed, you get the full benefits of the Visual Studio development experience.

For two-way data-binding expressions, use the *BindItem* variable:

```
<asp:FormView runat="server" ID="editCustomer">
<EditItemTemplate>
       <div>
           <asp:Label runat="server" AssociatedControlID="firstName">
               First Name:</asp:Label>
           <asp:TextBox ID="firstName" runat="server"
               Text='<%#BindItem.FirstName %>' />
       </div>
       <div>
           <asp:Label runat="server" AssociatedControlID="lastName">
               First Name:</asp:Label>
           <asp:TextBox ID="lastName" runat="server"
               Text='<%#BindItem.LastName %>' />
       </div>
       <asp:Button runat="server" CommandName="Update"/>
</EditItemTemplate>
</asp:FormView>
```

Most controls in the ASP.NET Web Forms framework that support data binding have been updated to support the *ItemType* property.

Model Binding

Model binding extends data binding in ASP.NET Web Forms controls to work with code-focused data access. It incorporates concepts from the *ObjectDataSource* control and from model binding in ASP.NET MVC.

Selecting data

To configure a data control to use model binding to select data, you set the control's *SelectMethod* property to the name of a method in the page's code. The data control calls the method at the appropriate time in the page life cycle and automatically binds the returned data. There's no need to explicitly call the *DataBind* method.

In the following example, the *GridView* control is configured to use a method named *GetCategories*:

```
<asp:GridView ID="categoriesGrid"
runat="server"
ItemType="WebApplication1.Model.Category"
SelectMethod="GetCategories" AutoGenerateColumns="false">
<Columns>
       <asp:BoundField DataField="CategoryID" HeaderText="ID" />
       <asp:BoundField DataField="CategoryName" HeaderText="Name" />
       <asp:BoundField DataField="Description" HeaderText="Description" />
       <asp:TemplateField HeaderText="# of Products">
           <ItemTemplate><%# Item.Products.Count %></ItemTemplate>
       </asp:TemplateField>
</Columns>
</asp:GridView>
```

You create the *GetCategories* method in the page's code. For a simple select operation, the method needs no parameters and should return an *IEnumerable* or *IQueryable* object. If the new *ItemType* property is set (which enables strongly typed data-binding expressions, as explained under Strongly Typed Data Controls earlier), the generic versions of these interfaces should be returned — *IEnumerable<T>* or *IQueryable<T>*, with the *T* parameter matching the type of the *ItemType* property (for example, *IQueryable<Category>*).

The following example shows the code for a *GetCategories* method. This example uses the Entity Framework Code First model with the Northwind sample database. The code makes sure that the query returns details of the related products for each category by way of the *Include* method. (This ensures that the *TemplateField* element in the markup displays the count of products in each category without requiring an n+1 select.)

```
public IQueryable<Category>
GetCategories()
{
    var db = new Northwind();
    return db.Categories.Include(c => c.Products);
}
```

When the page runs, the *GridView* control calls the *GetCategories* method automatically and renders the returned data using the configured fields:

ID	Name	Description	# of Products
1	Beverages	Soft drinks, coffees, teas, beers, and ales	13
2	Condiments	Sweet and savory sauces, relishes, spreads, and seasonings	12
3	Confections	Desserts, candies, and sweet breads	13
4	Dairy Products	Cheeses	10
5	Grains/Cereals	Breads, crackers, pasta, and cereal	7
6	Meat/Poultry	Prepared meats	6
7	Produce	Dried fruit and bean curd	5
8	Seafood	Seaweed and fish	12

Because the select method returns an *IQueryable* object, the *GridView* control can further manipulate the query before executing it. For example, the *GridView* control can add query expressions for sorting and paging to the returned *IQueryable* object before it is executed, so that those operations are performed by the underlying LINQ provider. In this case, Entity Framework will ensure those operations are performed in the database.

The following example shows the *GridView* control modified to allow sorting and paging:

```
<asp:GridView ID="categoriesGrid"
runat="server"
AutoGenerateColumns="false"
AllowSorting="true" AllowPaging="true" PageSize="5"
ItemType="WebApplication1.Model.Category" DataKeyNames="CategoryID"
SelectMethod="GetCategories"
UpdateMethod="UpdateCategory">
<Columns>
       <asp:BoundField DataField="CategoryID" HeaderText="ID" SortExpression="CategoryID" />
       <asp:BoundField DataField="CategoryName" HeaderText="Name" SortExpression="CategoryName" />
       <asp:BoundField DataField="Description" HeaderText="Description" />
       <asp:TemplateField HeaderText="# of Products">
           <ItemTemplate><%# Item.Products.Count %></ItemTemplate>
       </asp:TemplateField>
</Columns>
<EmptyDataTemplate>No categories found with a product count of
      <%# minProductsCount.SelectedValue %></EmptyDataTemplate>
</asp:GridView>
```

Now when the page runs, the control can make sure that only the current page of data is displayed and that it's ordered by the selected column:

ID	Name	Description	# of Products
3	Confections	Desserts, candies, and sweet breads	13
2	Condiments	Sweet and savory sauces, relishes, spreads, and seasonings	12
1	Beverages	Soft drinks, coffees, teas, beers, and ales	13
1 2			

To filter the returned data, parameters have to be added to the select method. These parameters will be populated by the model binding at run time, and you can use them to alter the query before returning the data.

For example, assume that you want to let users filter products by entering a keyword in the query string. You can add a parameter to the method and update the code to use the parameter value:

```
public IQueryable<Product>
GetProducts(string keyword)
{
    IQueryable<Product> query = _db.Products;

    if (!String.IsNullOrWhiteSpace(keyword))
    {
        query = query.Where(p => p.ProductName.Contains(keyword));
    }
    return query;
}
```

This code includes a *Where* expression if a value is provided for *keyword* and then returns the query results.

Value providers

The previous example was not specific about where the value for the *keyword* parameter was coming from. To indicate this information, you can use a parameter attribute. For this example, you can use the *QueryStringAttribute* class that's in the *System.Web.ModelBinding* namespace:

```
public IQueryable<Product>
GetProducts([QueryString]string keyword)
{
    IQueryable<Product> query = _db.Products;

    if (!String.IsNullOrWhiteSpace(keyword))
    {
        query = query.Where(p => p.ProductName.Contains(keyword));
    }
    return query;
}
```

This instructs model binding to try to bind a value from the query string to the *keyword* parameter at run time. (This might involve performing type conversion, although it doesn't in this case.) If a value cannot be provided and the type is non-nullable, an exception is thrown.

The sources of values for these methods are referred to as value providers, and the parameter attributes that indicate which value provider to use are referred to as value provider attributes. Web Forms will include value providers and corresponding attributes for all of the typical sources of user input in a Web Forms application, such as the query string, cookies, form values, controls, view state, session state, and profile properties. You can also write custom value providers.

By default, the parameter name is used as the key to find a value in the value provider collection. In the example, the code will look for a query-string value named keyword (for example, ~/default.aspx?keyword=chef). You can specify a custom key by passing it as an argument to the parameter attribute. For example, to use the value of the query-string variable named q, you could do this:

```
public IQueryable<Product>
GetProducts([QueryString("q")]string keyword)
{
    IQueryable<Product> query = _db.Products;

    if (!String.IsNullOrWhiteSpace(keyword))
    {
       query = query.Where(p => p.ProductName.Contains(keyword));
    }
    return query;
}
```

If this method is in the page's code, users can filter the results by passing a keyword using the query string:

Model binding accomplishes many tasks that you would otherwise have to code by hand: reading the value, checking for a null value, attempting to convert it to the appropriate type, checking whether the conversion was successful, and finally, using the value in the query. Model binding results in far less code and in the ability to reuse the functionality throughout your application.

Filtering by values from a control

Suppose you want to extend the example to let the user choose a filter value from a drop-down list. Add the following drop-down list to the markup and configure it to get its data from another method using the *SelectMethod* property:

```
<asp:Label runat="server" AssociatedControlID="categories"
Text="Select a category to show products for: " />
<asp:DropDownList runat="server" ID="categories"
SelectMethod="GetCategories" AppendDataBoundItems="true"
DataTextField="CategoryName" DataValueField="CategoryID"
AutoPostBack="true">
  <asp:ListItem Value="" Text="- all -" />
</asp:DropDownList>
```

Typically you would also add an *EmptyDataTemplate* element to the *GridView* control so that the control will display a message if no matching products are found:

```
<asp:GridView ID="productsGrid"
runat="server" DataKeyNames="ProductID"
AllowPaging="true" AllowSorting="true" AutoGenerateColumns="false"
SelectMethod="GetProducts" >
<Columns>
       <asp:BoundField DataField="ProductID" HeaderText="ID" />
       <asp:BoundField DataField="ProductName" HeaderText="Name"
            SortExpression="ProductName" />
       <asp:BoundField DataField="UnitPrice" HeaderText="Unit Price"
            SortExpression="UnitPrice" />
       <asp:BoundField DataField="UnitsInStock" HeaderText="# in Stock"
            SortExpression="UnitsInStock" />
</Columns>
<EmptyDataTemplate>
        No products matching the filter criteria were found</EmptyDataTemplate>
</asp:GridView>
```

In the page code, add the new select method for the drop-down list:

```
public IQueryable<Category>
GetCategories()
{
    return _db.Categories;
}
```

Finally, update the *GetProducts* select method to take a new parameter that contains the ID of the selected category from the drop-down list:

```
public IQueryable<Product>
GetProducts(
[QueryString("q")] string keyword,
[Control("categories")] int? categoryId)
{
    IQueryable<Product> query = _db.Products;

    if (!String.IsNullOrWhiteSpace(keyword))
    {
        query = query.Where(p => p.ProductName.Contains(keyword));
    }
    if (categoryId.HasValue && categoryId > 0)
    {
        query = query.Where(p => p.CategoryID == categoryId);
    }
    return query;
}
```

Now when the page runs, users can select a category from the drop-down list, and the *GridView* control is automatically re-bound to show the filtered data. This is possible because model binding tracks the values of parameters for select methods and detects whether any parameter value has changed after a postback. If so, model binding forces the associated data control to re-bind to the data.

Select a category to show products for: Confections

ID	Name	Unit Price	# in Stock
16	Pavlova	17.4500	29
19	Teatime Chocolate Biscuits	9.2000	25
20	Sir Rodney's Marmalade	81.0000	40
21	Sir Rodney's Scones	10.0000	3
25	NuNuCa Nuß-Nougat-Creme	14.0000	76
26	Gumbär Gummibärchen	31.2300	15
27	Schoggi Schokolade	43.9000	49
47	Zaanse koeken	9.5000	36
48	Chocolade	12.7500	15
49	Maxilaku	20.0000	10
1 2			

HTML Encoded Data-Binding Expressions

You can now HTML-encode the result of data-binding expressions. Add a colon (:) to the end of the <%# prefix that marks the data-binding expression:

```
<asp:TemplateField HeaderText="Name">
<ItemTemplate><%#: Item.Products.Name %></ItemTemplate>
</asp:TemplateField>
```

Unobtrusive Validation

You can now configure the built-in validator controls to use unobtrusive JavaScript for client-side validation logic. This significantly reduces the amount of JavaScript rendered inline in the page markup and reduces the overall page size. You can configure unobtrusive JavaScript for validator controls in any of these ways:

- Globally by adding the following setting to the *<appSettings>* element in the Web.config file:

  ```
  <add name="ValidationSettings:UnobtrusiveValidationMode" value="WebForms" />
  ```

- Globally by setting the static *System.Web.UI.ValidationSettings.UnobtrusiveValidationMode* property to *UnobtrusiveValidationMode.WebForms* (typically in the *Application_Start* method in the Global.asax file).
- Individually for a page by setting the new *UnobtrusiveValidationMode* property of the *Page* class to *UnobtrusiveValidationMode.WebForms*.

HTML5 Updates

Some improvements have been made to Web Forms server controls to take advantage of new features of HTML5:

- The *TextMode* property of the *TextBox* control has been updated to support the new HTML5 input types like *email*, *datetime*, and so on.
- The *FileUpload* control now supports multiple file uploads from browsers that support this HTML5 feature.
- Validator controls now support validating HTML5 input elements.
- New HTML5 elements that have attributes that represent a URL now support runat="server". As a result, you can use ASP.NET conventions in URL paths, like the ~ operator to represent the application root (for example, <video runat="server" src="~/myVideo.wmv" />).
- The *UpdatePanel* control has been fixed to support posting HTML5 input fields.

ASP.NET MVC 4

ASP.NET MVC 4 Beta is now included with Visual Studio 11 Beta. ASP.NET MVC is a framework for developing highly testable and maintainable Web applications by leveraging the Model-View-Controller (MVC) pattern. ASP.NET MVC 4 makes it easy to build applications for the mobile Web and includes ASP.NET Web API, which helps

you build HTTP services that can reach any device. For more information, see the ASP.NET MVC 4 Release Notes.

ASP.NET Web Pages 2

New features include the following:

- New and updated site templates.
- Adding server-side and client-side validation using the *Validation* helper.
- The ability to register scripts using an assets manager.
- Enabling logins from Facebook and other sites using OAuth and OpenID.
- Adding maps using the *Maps* helper.
- Running Web Pages applications side-by-side.
- Rendering pages for mobile devices.

For more information about these features and full-page code examples, see The Top Features in Web Pages 2 Beta.

Visual Web Developer 11 Beta

This section provides information about improvements for web development in Visual Web Developer 11 Beta and Visual Studio 2012 Release Candidate.

Project Sharing Between Visual Studio 2010 and Visual Studio 2012 Release Candidate (Project Compatibility)

Until Visual Studio 2012 Release Candidate, opening an existing project in a newer version of Visual Studio launched the Conversion Wizard. This forced an upgrade of the content (assets) of a project and solution to new formats that were not backward compatible. Therefore, after the conversion you could not open the project in the older version of Visual Studio.

Many customers have told us that this was not the right approach. In Visual Studio 11 Beta, we now support sharing projects and solutions with Visual Studio 2010 SP1. This means that if you open a 2010 project in Visual Studio 2012 Release Candidate, you will still be able to open the project in Visual Studio 2010 SP1.

> **NOTE**
> A few types of projects cannot be shared between Visual Studio 2010 SP1 and Visual Studio 2012 Release Candidate. These include some older projects (such as ASP.NET MVC 2 projects) or projects for special purposes (such as Setup projects).

When you open a Visual Studio 2010 SP1 Web project for the first time in Visual Studio 11 Beta, the following properties are added to the project file:

- FileUpgradeFlags
- UpgradeBackupLocation
- OldToolsVersion
- VisualStudioVersion
- VSToolsPath

FileUpgradeFlags, UpgradeBackupLocation, and OldToolsVersion are used by the process that upgrades the project file. They have no impact on working with the project in Visual Studio 2010.

VisualStudioVersion is a new property used by MSBuild 4.5 that indicates the version of Visual Studio for the current project. Because this property didn't exist in MSBuild 4.0 (the version of MSBuild that Visual Studio 2010 SP1 uses), we inject a default value into the project file.

The VSToolsPath property is used to determine the correct .targets file to import from the path represented by the MSBuildExtensionsPath32 setting.

There are also some changes related to Import elements. These changes are required in order to support compatibility between both versions of Visual Studio.

> **NOTE**
> If a project is being shared between Visual Studio 2010 SP1 and Visual Studio 11 Beta on two different computers, and if the project includes a local database in the App_Data folder, you must make sure that the version of SQL Server used by the database is installed on both computers.

Configuration Changes in ASP.NET 4.5 Website Templates

The following changes have been made to the default *Web.config* file for site that are created using website templates in Visual Studio 2012 Release Candidate:

- In the `<httpRuntime>` element, the `encoderType` attribute is now set by default to use the AntiXSS types that were added to ASP.NET. For details, see AntiXSS Library.
- Also in the `<httpRuntime>` element, the `requestValidationMode` attribute is set to "4.5". This means that by default, request validation is configured to use deferred ("lazy") validation. For details, see New ASP.NET Request Validation Features.
- The `<modules>` element of the `<system.webServer>` section does not contain a `runAllManagedModulesForAllRequests` attribute. (Its default value is false.) This means that if you are using a version of IIS 7 that has not been updated to SP1, you might have issues with routing in a new site. For more information, see Native Support in IIS 7 for ASP.NET Routing.

These changes do not affect existing applications. However, they might represent a difference in behavior between existing websites and new websites that you create for ASP.NET 4.5 using the new templates.

Native Support in IIS 7 for ASP.NET Routing

This is not a change to ASP.NET as such, but a change in templates for new website projects that can affect you if you are working a version of IIS 7 that has not had the SP1 update applied.

In ASP.NET, you can add the following configuration setting to applications in order to support routing:

```
<configuration>
  <system.webServer>
<modules runAllManagedModulesForAllRequests="true">
     <!-- more -->
</modules>
  </system.webServer>
</configuration>
```

When **runAllManagedModulesForAllRequests** is true, a URL like `http://mysite/myapp/home` goes to ASP.NET, even though there is no *.aspx*, *.mvc*, or similar extension on the URL.

An update that was made to IIS 7 makes the **runAllManagedModulesForAllRequests** setting unnecessary and supports ASP.NET routing natively. (For information about the update, see the Microsoft Support article An update is available that enables certain IIS 7.0 or IIS 7.5 handlers to handle requests whose URLs do not end with a period.)

If your website is running on IIS 7 and if IIS has been updated, you do not need to set **runAllManagedModulesForAllRequests** to true. In fact, setting it to true is not recommended, because it adds unnecessary processing overhead to request. When this setting is true, all requests, including those for *.htm*, *.jpg*, and other static files, also go through the ASP.NET request pipeline.

If you create a new ASP.NET 4.5 website using the templates that are provided in Visual Studio 2012 RC, the configuration for the website does not include the **runAllManagedModulesForAllRequests** setting. This means that by default the setting is false.

If you then run the website on Windows 7 without SP1 installed, IIS 7 will not include the required update. As a consequence, routing will not work and you will see errors. If you have a problem where routing does not work, you can do either the following:

- Update Windows 7 to SP1, which will add the update to IIS 7.
- Install the update that's described in the Microsoft Support article listed previously.
- Set **runAllManagedModulesForAllRequests** to true in that website's Web.config file. Note that this will add some overhead to requests.

HTML Editor

Smart Tasks

In Design view, complex properties of server controls often have associated dialog boxes and wizards to make it easy to set them. For example, you can use a special dialog box to add a data source to a *Repeater* control or add columns to a *GridView* control.

However, this type of UI help for complex properties has not been available in Source view. Therefore, Visual Studio 11 introduces Smart Tasks for Source view. Smart Tasks are context-aware shortcuts for commonly used features in the C# and Visual Basic editors.

For ASP.NET Web Forms controls, Smart Tasks appear on server tags as a small glyph when the insertion point is inside the element:

```
<asp:GridView runat="server" />
```

The Smart Task expands when you click the glyph or press CTRL+. (dot), just as in the code editors. It then displays shortcuts that are similar to the Smart Tasks in Design view.

For example, the Smart Task in the previous illustration shows the GridView Tasks options. If you choose Edit Columns, the following dialog box is displayed:

Filling in the dialog box sets the same properties you can set in Design view. When you click OK, the markup for the control is updated with the new settings:

```
<asp:GridView runat="server">
    <Columns>
        <asp:HyperLinkField Target="_blank"
            Text="Click me"
            AccessibleHeaderText="Go to the URL"
            HeaderText="Link"></asp:HyperLinkField>
    </Columns>
</asp:GridView>
```

WAI-ARIA support

Writing accessible websites is becoming increasingly important. The WAI-ARIA accessibility standard defines how developers should write accessible websites. This standard is now fully supported in Visual Studio.

For example, the *role* attribute now has full IntelliSense:

```
<nav role="menu">
    <ul>
        <li role="menuitem"></li>
    </ul>
</nav>
```

The WAI-ARIA standard also introduces attributes that are prefixed with *aria-* that let you add semantics to an HTML5 document. Visual Studio also fully supports these *aria-* attributes:

New HTML5 snippets

To make it faster and easier to write commonly used HTML5 markup, Visual Studio includes a number of snippets. An example is the video snippet:

To invoke the snippet, press Tab twice when the element is selected in IntelliSense:

```
<video controls="controls">
    <source src="file.mp4" type="video/mp4" />
    <source src="file.webm" type="video/webm" />
    <source src="file.ogv" type="video/ogg" />
</video>
```

This produces a snippet that you can customize.

Extract to user control

In large web pages, it can be a good idea to move individual pieces into user controls. This form of refactoring can help increase the readability of the page and can simplify the page structure.

To make this easier, when you edit Web Forms pages in Source view, you can now select text in a page, right-click it, and then choose Extract to User Control:

IntelliSense for code nuggets in attributes

Visual Studio has always provided IntelliSense for server-side code nuggets in any page or control. Now Visual Studio includes IntelliSense for code nuggets in HTML attributes as well.

```
<div class="<%= Request.q %>"
```

Path
PathInfo
PhysicalApplicationPath
PhysicalPath
QueryString
RawUrl
ReadEntityBodyMode
RequestContext
RequestType

This makes it easier to create data-binding expressions:

```
<asp:repeater runat="server">
    <itemtemplate>
        <input value="<%# HttpUtility. %>"
    </itemtemplate>
</asp:repeater>
```

Equals
HtmlAttributeEncode
HtmlDecode
HtmlEncode
JavaScriptStringEncode
ParseQueryString
ReferenceEquals
UrlDecode
UrlDecodeToBytes

Automatic renaming of matching tag when you rename an opening or closing tag

If you rename an HTML element (for example, you change a *div* tag to be a *header* tag), the corresponding opening or closing tag also changes in real time.

```
<heade>
    <hgroup>
        <h1>Coffee Shop</h1>
        <h2>Best coffee in town!</h2>
    </hgroup>
</heade>
```

This helps avoid the error where you forget to change a closing tag or change the wrong one.

Event handler generation

Visual Studio now includes features in Source view to help you write event handlers and bind them manually. If you are editing an event name in Source view, IntelliSense displays <Create New Event>, which will create an event handler in the page's code that has the right signature:

```
<asp:Button ID="btnSave" runat="server" OnClick="" />
```

<Create New Event>

By default, the event handler will use the control's ID for the name of the event-handling method:

```
<asp:Button ID="btnSave" runat="server" OnClick="btnSave_Click" />
```

The resulting event handler will look like this (in this case, in C#):

```
protected void btnSave_Click(object sender, EventArgs e)
{

}
```

Smart indent

When you press Enter while inside an empty HTML element, the editor will put the insertion point in the right

place:

```
<div></div>
```

If you press Enter in this location, the closing tag is moved down and indented to match the opening tag. The insertion point is also indented:

```
<div>
    |
</div>
```

Auto-reduce statement completion

The IntelliSense list in Visual Studio now filters based on what you type so that it displays only relevant options:

IntelliSense also filters based on the title case of the individual words in the IntelliSense list. For example, if you type "dl", both dl and asp:DataList are displayed:

This feature makes it faster to get statement completion for known elements.

JavaScript Editor

The JavaScript editor in Visual Studio 2012 Release Candidate is completely new and it greatly improves the experience of working with JavaScript in Visual Studio.

Code outlining

Outlining regions are now automatically created for all functions, allowing you to collapse parts of the file that aren't pertinent to your current focus.

Brace matching

When you put the insertion point on an opening or closing brace, the editor highlights the matching one.

Go to Definition

The Go to Definition command lets you jump to the source for a function or variable.

ECMAScript5 support

The editor supports the new syntax and APIs in ECMAScript5, the latest version of the standard that describes the JavaScript language.

DOM IntelliSense

IntelliSense for DOM APIs has been improved, with support for many new HTML5 APIs including *querySelector*, DOM Storage, cross-document messaging, and *canvas*. DOM IntelliSense is now driven by a single simple JavaScript file, rather than by a native type library definition. This makes it easy to extend or replace.

VSDOC signature overloads

Detailed IntelliSense comments can now be declared for separate overloads of JavaScript functions by using the new *<signature>* element, as shown in this example:

```
function GetOrSet(key, value) {
/// <signature>
///  <summary>Gets the value</summary>
///  <param name="key" type="String">The key to get the value for</param>
///  <returns type="String" />
/// </signature>
/// <signature>
///  <summary>Sets the value</summary>
///  <param name="key" type="String">The key to set the value for</param>
///  <param name="value" type="String">The value to set</param>
///  <returns type="MyLib" />
/// </signature>
    if (value) {
        values[key] = value;
        return this;
    } else {
        return values[key];
    }
}
```

Implicit references

You can now add JavaScript files to a central list that will be implicitly included in the list of files that any given JavaScript file or block references, meaning you'll get IntelliSense for its contents. For example, you can add jQuery files to the central list of files, and you'll get IntelliSense for jQuery functions in any JavaScript block of file, whether you've referenced it explicitly (using /// <reference />) or not.

CSS Editor

Auto-reduce statement completion

The IntelliSense list for CSS now filters based on the CSS properties and values supported by the selected schema.

IntelliSense also supports title case searches:

Hierarchical indentation

The CSS editor uses indentation to display hierarchical rules, which gives you an overview of how the cascading rules are logically organized. In the following example, the #list a selector is a cascading child of list and is therefore indented.

```
#list
{
    color: #f00;
}

    #list a
    {
        text-decoration: none;
    }
```

The following example shows more complex inheritance:

```
#list
{
    color: #f00;
}

    #list a
    {
        text-decoration: none;
    }

    #list div
    {
        color: #f00;
    }

        #list div a
        {
            text-decoration: none;
        }

    #list footer
    {
        color: #f00;
    }
```

The indentation of a rule is determined by its parent rules. Hierarchical indentation is enabled by default, but you can disable it the Options dialog box (Tools, Options from the menu bar):

CSS hacks support

Analysis of hundreds of real-world CSS files shows that CSS hacks are very common, and now Visual Studio supports the most widely used ones. This support includes IntelliSense and validation of the star (*) and underscore (_) property hacks:

Typical selector hacks are also supported so that hierarchical indentation is maintained even when they are applied. A typical selector hack used to target Internet Explorer 7 is to prepend a selector with **:first-child + html*. Using that rule will maintain the hierarchical indentation:

```
#menu {
    list-style-type: none;
}

    *:first-child + html #menu li {
        margin: 0;
        float: left;
    }
```

Vendor specific schemas (-moz-, -webkit)

CSS3 introduces many properties that have been implemented by different browsers at different times. This previously forced developers to code for specific browsers by using vendor-specific syntax. These browser-specific properties are now included in IntelliSense.

Commenting and uncommenting support

You can now comment and uncomment CSS rules using the same shortcuts that you use in the code editor (Ctrl+K,C to comment and Ctrl+K,U to uncomment).

Color picker

In previous versions of Visual Studio, IntelliSense for color-related attributes consisted of a drop-down list of named color values. That list has been replaced by a full-featured color picker.

When you enter a color value, the color picker is displayed automatically and presents a list of previously used colors followed by a default color palette. You can select a color using the mouse or the keyboard.

The list can be expanded into a complete color picker. The picker lets you control the alpha channel by automatically converting any color into RGBA when you move the opacity slider:

```
body
{
    background: rgba(123, 53, 45, .3);
    border-color: silver;
    text-decoration-color: hsl(240, 100%, 50%);
    color: rgba(255, 255, 255, 0.76)
}
```

Snippets

Snippets in the CSS editor make it easier and faster to create cross-browser styles. Many CSS3 properties that require browser-specific settings have now been rolled into snippets.

```
body
{
    -ms-transition-timing-function: ease-in-out;
    -moz-transition-timing-function: ease-in-out;
    -o-transition-timing-function: ease-in-out;
    -webkit-transition-timing-function: ease-in-out;
    transition-timing-function: ease-in-out;
}
```

CSS snippets support advanced scenarios (like CSS3 media queries) by typing the at-symbol (@), which shows the IntelliSense list.

When you select @media value and press Tab, the CSS editor inserts the following snippet:

```
@media only screen and (max-width: 1024px) and (max-height: 768px) {

}
```

As with snippets for code, you can create your own CSS snippets.

Custom regions

Named code regions, which are already available in the code editor, are now available for CSS editing. This lets you easily group related style blocks.

```
/*#region Menu */

#menu {
    list-style-type: none;
}

    #menu li {
        margin: 0;
        float:left;
    }

/*#endregion */
```

When a region is collapsed it displays the name of the region:

```
Menu
```

Page Inspector

Page Inspector is a tool that renders a web page (HTML, Web Forms, ASP.NET MVC, or Web Pages) in the Visual Studio IDE and lets you examine both the source code and the resulting output. For ASP.NET pages, Page Inspector lets you determine which server-side code has produced the HTML markup that is rendered to the browser.

For more information about Page Inspector, please see the following tutorials:

- Using Page Inspector in ASP.NET MVC
- Using Page Inspector in ASP.NET Web Forms

Publishing

Publish profiles

In Visual Studio 2010, publishing information for Web application projects is not stored in version control and is not designed for sharing with others. In Visual Studio 2012 Release Candidate, the format of the publish profile has been changed. It has been made a team artifact, and it is now easy to leverage from builds based on MSBuild. Build configuration information is in the Publish dialog box so that you can easily switch build configurations before publishing.

Publish profiles are stored in the PublishProfiles folder. The location of the folder depends on what programming language you are using:

- C#: Properties\PublishProfiles
- Visual Basic: My Project\PublishProfiles

Each profile is an MSBuild file. During publishing, this file is imported into the project's MSBuild file. In Visual Studio 2010, if you want to make changes to the publish or package process, you have to put your customizations in a file named **ProjectName**.wpp.targets. This is still supported, but you can now put your customizations in the publish profile itself. That way, the customizations will be used only for that profile.

You can now also leverage publish profiles from MSBuild. To do so, use the following command when you build the project:

```
msbuild.exe project.csproj /t:WebPublish /p:PublishProfile=ProfileName
```

The project.csproj value is the path of the project, and ProfileName is the name of the profile to publish. Alternatively, instead of passing the profile name for the *PublishProfile* property, you can pass in the full path to the publish profile.

ASP.NET precompilation and merge

For Web application projects, Visual Studio 2012 Release Candidate adds an option on the Package/Publish Web properties page that lets you precompile and merge your site's content when you publish or package the project. To see these options, right-click the project in Solution Explorer, choose Properties, and then choose the Package/Publish Web property page. The following illustration shows the Precompile this application before publishing option.

When this option is selected, Visual Studio precompiles the application whenever you publish or package the web application. If you want to control how the site is precompiled or how assemblies are merged, click the Advanced button to configure those options.

IIS Express

The default web server for testing web projects in Visual Studio is now IIS Express. The Visual Studio Development Server is still an option for local web server during development, but IIS Express is now the recommended server. The experience of using IIS Express in Visual Studio 11 Beta is very similar to using it in Visual Studio 2010 SP1.
